$a \sqrt{r}$  is approximately proportional to the discharge. It is a maximum at  $208^\circ$ , corresponding to  $\frac{19}{20}$  of the diameter, and the flow of a conduit  $\frac{19}{20}$  full is about 5 per cent greater than that of one completely filled.

**Table giving Fall in Feet per Mile, the Distance on Slope corresponding to a Fall of 1 Ft., and also the Values of  $s$  and  $\sqrt{s}$  for Use in the Formula  $v = c \sqrt{rs}$ .**

$s = H \div L$  = sine of angle of slope = fall of water-surface ( $H$ ), in any distance ( $L$ ), divided by that distance.

Fall in Feet per Mi.	Slope, 1 Foot in	Sine of Slope, $s$ .	$\sqrt{s}$ .	Fall in Feet per Mi.	Slope, 1 Foot in	Sine of Slope, $s$ .	$\sqrt{s}$ .

**Values of the Coefficient  $c$ .** (Chiefly condensed from P. J. Flynn on Flow of Water.)—Almost all the old hydraulic formulæ for finding the mean velocity in open and closed channels have constant coefficients, and are therefore correct for only a small range of channels. They have often been found to give incorrect results with disastrous effects. Ganguillet and Kutter thoroughly investigated the American, French, and other experiments, and they gave as the result of their labors the formula now generally known as Kutter's formula. There are so many varying conditions affecting the flow of water, that all hydraulic formulæ are only approximations to the correct result.

When the surface-slope measurement is good, Kutter's formula will give results seldom exceeding  $7\frac{1}{2}\%$  error, provided the rugosity coefficient of the formula is known for the site. For small open channels D'Arcy's and Bazin's formulæ, and for cast-iron pipes D'Arcy's formulæ, are generally accepted as being approximately correct.

**Kutter's Formula** for measures in feet is

$$v = \left\{ \frac{\frac{1.811}{n} + 41.6 + \frac{.00281}{s}}{1 + \left(41.6 + \frac{.00281}{s}\right) \times \frac{n}{\sqrt{r}}} \right\} \times \sqrt{rs},$$

in which  $v$  = mean velocity in feet per second;  $r = \frac{a}{p}$  = hydraulic mean

depth in feet = area of cross-section in square feet divided by wetted perimeter in lineal feet ;  $s$  = fall of water-surface ( $h$ ) in any distance ( $l$ ) divided by that distance,  $= \frac{h}{l}$ , = sine of slope ;  $n$  = the coefficient of rugosity, depending on the nature of the lining or surface of the channel. If we let the first term of the right-hand side of the equation equal  $c$ , we have Chezy's formula,  $v = c \sqrt{rs} = c \times \sqrt{r} \times \sqrt{s}$ .

**Values of  $n$  in Kutter's Formula.**—The accuracy of Kutter's formula depends, in a great measure, on the proper selection of the coefficient of roughness  $n$ . Experience is required in order to give the right value to this coefficient, and to this end great assistance can be obtained, in making this selection, by consulting and comparing the results obtained from experiments on the flow of water already made in different channels.

In some cases it would be well to provide for the contingency of future deterioration of channel, by selecting a high value of  $n$ , as, for instance, where a dense growth of weeds is likely to occur in small channels, and also where channels are likely not to be kept in a state of good repair.

The following table, giving the value of  $n$  for different materials, is compiled from Kutter, Jackson, and Hering, and this value of  $n$  applies also in each instance, to the surfaces of other materials equally rough.

#### VALUE OF $n$ IN KUTTER'S FORMULA FOR DIFFERENT CHANNELS.

$n = .009$ , well-planed timber, in perfect order and alignment ; otherwise, perhaps .01 would be suitable.

$n = .010$ , plaster in pure cement ; planed timber ; glazed, coated, or enamelled stoneware and iron pipes ; glazed surfaces of every sort in perfect order.

$n = .011$ , plaster in cement with one third sand, in good condition ; also for iron, cement, and terra-cotta pipes, well joined, and in best order.

$n = .012$ , unplanned timber, when perfectly continuous on the inside ; flumes.

$n = .013$ , ashlar and well-laid brickwork ; ordinary metal ; earthen and stoneware pipe in good condition, but not new ; cement and terra-cotta pipe not well jointed nor in perfect order, plaster and planed wood in imperfect or inferior condition ; and, generally, the materials mentioned with  $n = .010$ , when in imperfect or inferior condition.

$n = .015$ , second class or rough-faced brickwork ; well-dressed stonework ; foul and slightly tuberculated iron ; cement and terra-cotta pipes, with imperfect joints and in bad order ; and canvas lining on wooden frames.

$n = .017$ , brickwork, ashlar, and stoneware in an inferior condition ; tuberculated iron pipes ; rubble in cement or plaster in good order ; fine gravel, well rammed,  $\frac{1}{3}$  to  $\frac{2}{3}$  inch diameter ; and, generally, the materials mentioned with  $n = .013$  when in bad order and condition.

$n = .020$ , rubble in cement in an inferior condition ; coarse rubble, rough set in a normal condition ; coarse rubble set dry ; ruined brickwork and masonry ; coarse gravel well rammed, from 1 to  $1\frac{1}{2}$  inch diameter ; canals with beds and banks of very firm, regular gravel, carefully trimmed and rammed in defective places ; rough rubble with bed partially covered with silt and mud ; rectangular wooden troughs, with battens on the inside two inches apart ; trimmed earth in perfect order.

$n = .0225$ , canals in earth above the average in order and regimen.

$n = .025$ , canals and rivers in earth of tolerably uniform cross-section ; slope and direction, in moderately good order and regimen, and free from stones and weeds.

$n = .0275$ , canals and rivers in earth below the average in order and regimen.

$n = .030$ , canals and rivers in earth in rather bad order and regimen, having stones and weeds occasionally, and obstructed by detritus.

$n = .035$ , suitable for rivers and canals with earthen beds in bad order and regimen, and having stones and weeds in great quantities.

$n = .05$ , torrents encumbered with detritus.

Kutter's formula has the advantage of being easily adapted to a change in the surface of the pipe exposed to the flow of water, by a change in the value of  $n$ . For cast-iron pipes it is usual to use  $n = .013$  to provide for the future deterioration of the surface.

Reducing Kutter's formula to the form  $v = c \times \sqrt{r} \times \sqrt{s}$ , and taking  $n$ , the coefficient of roughness in the formula = .011, .012, and .013, and  $s = .001$ , we have the following values of the coefficient  $c$  for different diameters of conduit.

**Values of  $c$  in Formula  $v = c \times \sqrt{r} \times \sqrt{s}$  for Metal Pipes and Moderately Smooth Conduits Generally.**

By KUTTER'S FORMULA ( $s = .001$  or greater.)

Diameter.			$n = .011$	$n = .012$	$n = .013$	Diameter.			$n = .011$	$n = .012$	$n = .013$
ft.	in.	$c =$	$c =$	$c =$	$c =$	ft.	in.	$c =$	$c =$	$c =$

For circular pipes the hydraulic mean depth  $r$  equals  $\frac{1}{4}$  of the diameter. According to Kutter's formula the value of  $c$ , the coefficient of discharge, is the same for all slopes greater than 1 in 1000; that is, within these limits  $c$  is constant. We further find that up to a slope of 1 in 2640 the value of  $c$  is, for all practical purposes, constant, and even up to a slope of 1 in 5000 the difference in the value of  $c$  is very little. This is exemplified in the following:

**Value of  $c$  for Different Values of  $\sqrt{r}$  and  $s$  in Kutter's Formula, with  $n = .013$ .**

$$v = c \sqrt{r} \times \sqrt{s}.$$

$\sqrt{r}$	Slopes.				
	1 in 1000	1 in 2500	1 in 3333.3	1 in 5000	1 in 10,000
.6	93.6	91.5	90.4	88.4	83.3
1	116.5	115.2	114.4	113.2	109.7
2	142.6	142.8	143.0	143.1	143.8

The reliability of the values of the coefficient of Kutter's formula for pipes of less than 6 in. diameter is considered doubtful. (See note under table on page 564.)

**Values of  $c$  for Earthen Channels, by Kutter's Formula, for Use in Formula  $v = c \sqrt{rs}$ .**

Mr. Molesworth, in the 22d edition of his "Pocket-book of Engineering Formulæ," gives a modification of Kutter's formula as follows: For flow in cast-iron pipes,  $v = c \sqrt{rs}$ , in which

$$c = \frac{181 + \frac{.00281}{s}}{1 + \frac{.026}{\sqrt{d}} \left( 41.6 + \frac{.00281}{s} \right)}$$

in which  $d$  = diameter of the pipe in feet.

(This formula was given incorrectly in Molesworth's 21st edition.)

**Molesworth's Formula.**— $v = \sqrt{krs}$ , in which the values of  $k$  are as follows:

Nature of Channel.	Values of $k$ for Velocities.	
	Less than 4 ft. per sec.	More than 4 ft. per sec.
Brickwork.....	8800	8500
Earth.....	7200	6800
Shingle.....	6400	5900
Rough, with bowlders.....	5300	4700

In very large channels, rivers, etc., the description of the channel affects the result so slightly that it may be practically neglected, and  $k$  assumed = from 8500 to 9000.

**Flynn's Formula.**—Mr. Flynn obtains the following expression of the value of Kutter's coefficient for a slope of .001 and a value of  $n = .013$ :

$$c = \frac{183.72}{1 + \left( 44.41 \times \frac{.013}{\sqrt{r}} \right)}$$

The following table shows the close agreement of the values of  $c$  obtained from Kutter's, Molesworth's, and Flynn's formulæ:

Diameter.	Slope.	Kutter.	Molesworth.	Flynn.
6 inches	1 in 40	71.50	71.48	69.5
6 inches	1 in 1000	69.50	69.79	69.5
4 feet	1 in 400	117.	117.	116.5
4 feet	1 in 1000	116.5	116.55	116.5
8 feet	1 in 700	130.5	130.68	130.5
8 feet	1 in 2600	129.8	129.93	130.5

Mr. Flynn gives another simplified form of Kutter's formula for use with different values of  $n$  as follows:

$$v = \left( \frac{K}{1 + \left( 44.41 \times \frac{n}{\sqrt{r}} \right)} \right) \sqrt{rs}.$$

In the following table the value of  $K$  is given for the several values of  $n$ :

$n$	$K$	$n$	$K$	$n$	$K$	$n$	$K$	$n$	$K$
.009	245.63	.012	195.33	.015	165.14	.018	145.03	.021	130.65
.010	225.51	.013	183.72	.016	157.6	.019	139.73	.022	126.73
.011	209.05	.014	187.77	.017	150.94	.020	134.96	.0225	124.9

If in the application of Mr. Flynn's formula given above within the limits of  $n$  as given in the table, we substitute for  $n$ ,  $K$ , and  $\sqrt{r}$  their values, we have a simplified form of Kutter's formula.

For instance, when  $n = .011$ , and  $d = 3$  feet, we have

$$v = \frac{209.05}{1 + \left(44.41 \times \frac{.011}{.866}\right)} \times \sqrt[4]{rs}.$$

### Bazin's Formulæ:

For very even surfaces, fine plastered sides and bed, planed planks, etc.,

$$v = \sqrt[4]{1 \div .0000045 \left(10.16 + \frac{1}{r}\right)} \times \sqrt[4]{rs}.$$

For even surfaces such as cut-stone, brickwork, unplanned planking, mortar, etc.:

$$v = \sqrt[4]{1 \div .000013 \left(4.354 + \frac{1}{r}\right)} \times \sqrt[4]{rs}.$$

For slightly uneven surfaces, such as rubble masonry:

$$v = \sqrt[4]{1 \div .00006 \left(1.219 + \frac{1}{r}\right)} \times \sqrt[4]{rs}.$$

For uneven surfaces, such as earth:

$$v = \sqrt[4]{1 \div .00035 \left(0.2438 + \frac{1}{r}\right)} \times \sqrt[4]{rs}.$$

A modification of Bazin's formula, known as D'Arcy's Bazin's:

$$v = r \sqrt[4]{\frac{1000s}{.08534r + 0.35}}.$$

For small channels of less than 20 feet bed Bazin's formula for earthen channels in good order gives very fair results, but Kutter's formula is superseding it in almost all countries where its accuracy has been investigated.

The last table on p. 561 shows the value of  $c$ , in Kutter's formula, for a wide range of channels in earth, that will cover anything likely to occur in the ordinary practice of an engineer.

**D'Arcy's Formula** for clean iron pipes under pressure is

$$v = \left\{ \frac{rs}{.00007726 + \frac{.00000162}{r}} \right\}^{\frac{1}{2}}$$

Flynn's modification of D'Arcy's formula is

$$v = \left( \frac{.155256d}{12d + 1} \right)^{\frac{1}{2}} \times \sqrt[4]{rs},$$

in which  $d =$  diameter in feet.

D'Arcy's formula, as given by J. B. Francis, C.E., for old cast-iron pipe, lined with deposit and under pressure, is

$$v = \left( \frac{144d^2s}{.0082(12d + 1)} \right)^{\frac{1}{2}}.$$

Flynn's modification of D'Arcy's formula for old cast-iron pipe is

$$v = \left( \frac{70243.9d}{12d + 1} \right)^{\frac{1}{2}} \times \sqrt[4]{rs}.$$

**For Pipes Less than 5 inches in Diameter,** coefficients ( $c$ ) in the formula  $v = c \sqrt{rs}$ , from the formula of D'Arcy, Kutter, and Fanning.

Diam. in inches.	D'Arcy, for Clean Pipes.	Kutter, for $n = .011$ $s = .001$	Fanning, for Clean Iron Pipes	Diam. in inches	D'Arcy, for Clean Pipes.	Kutter, for $n = .011$ $s = .001$	Fanning, for Clean Iron Pipes.
$\frac{3}{8}$	59.4	32.		$1\frac{3}{4}$	90.7	58.8	92.5
$\frac{1}{2}$	65.7	36.1		2	92.9	61.5	94.8
$\frac{3}{4}$	74.5	42.6		$2\frac{1}{2}$	96.1	66.	
1	80.4	47.4	80.4	3	98.5	70.1	96.6
$1\frac{1}{4}$	84.8	51.9		4	101.7	77.4	103.4
$1\frac{1}{2}$	88.1	55.4	88.	5	103.8	82.9	

Mr. Flynn, in giving the above table, says that the facts show that the coefficients diminish from a diameter of 5 inches to smaller diameters, and it is a safer plan to adopt coefficients varying with the diameter than a constant coefficient. No opinion is advanced as to what coefficients should be used with Kutter's formula for small diameters. The facts are simply stated, giving the results of well-known authors.

**Older Formulæ.**—The following are a few of the many formulæ for flow of water in pipes given by earlier writers. As they have constant coefficients, they are not considered as reliable as the newer formulæ.

$$\text{Prony, } v = 97 \sqrt{rs} - .08;$$

$$\text{Eytelwein, } v = 50 \sqrt{\frac{dh}{l + 50d}}, \text{ or } v = 108 \sqrt{rs} - 0.13;$$

$$\text{Hawksley, } v = 48 \sqrt{\frac{dh}{l + 54d}}; \text{ Neville, } v = 140 \sqrt{rs} - 11 \sqrt[3]{rs}.$$

In these formulæ  $d$  = diameter in feet;  $h$  = head of water in feet;  $l$  = length of pipe in feet;  $s$  = sine of slope =  $\frac{h}{l}$ ;  $r$  = mean hydraulic depth,

= area  $\div$  wet perimeter =  $\frac{d}{4}$  for circular pipe.

Mr. Santo Crimp (*Eng'g*, August 4, 1893) states that observations on flow in brick sewers show that the actual discharge is 33% greater than that calculated by Eytelwein's formula. He thinks Kutter's formula not superior to D'Arcy's for brick sewers, the usual coefficient of roughness in the former, viz., .013, being too low for large sewers and far too small in the case of small sewers.

D'Arcy's formula for brickwork is

$$v = \frac{\sqrt{2g}}{m} rs; \quad m = a \left( 1 + \frac{B}{r} \right); \quad a = .0037285; \quad B = .229663.$$

## VELOCITY OF WATER IN OPEN CHANNELS.

**Irrigation Canals.**—The minimum mean velocity required to prevent the deposit of silt or the growth of aquatic plants is in Northern India taken at  $1\frac{1}{2}$  feet per second. It is stated that in America a higher velocity is required for this purpose, and it varies from 2 to  $3\frac{1}{2}$  feet per second. The maximum allowable velocity will vary with the nature of the soil of the bed. A sandy bed will be disturbed if the velocity exceeds 3 feet per second. Good loam with not too much sand will bear a velocity of 4 feet per second. The Cavour Canal in Italy, over a gravel bed, has a velocity of about 5 per second. (Flynn's "Irrigation Canals.")

**Mean Surface and Bottom Velocities.**—According to the formula of Bazin,

$$v = v_{\max} - 25.4 \sqrt{rs}; \quad v = v_b + 10.87 \sqrt{rs}.$$

$\therefore v_b = v - 10.87 \sqrt{rs}$ , in which  $v$  = mean velocity in feet per second,  $v_{max}$  = maximum surface velocity in feet per second,  $v_b$  = bottom velocity in feet per second,  $r$  = hydraulic mean depth in feet = area of cross-section in square feet divided by wetted perimeter in feet,  $s$  = sine of slope.

The least velocity, or that of the particles in contact with the bed, is almost as much less than the mean velocity as the greatest velocity is greater than the mean.

Rankine states that in ordinary cases the velocities may be taken as bearing to each other nearly the proportions of 3, 4, and 5. In very slow currents they are nearly as 2, 3, and 4.

**Safe Bottom and Mean Velocities.**—Ganguillet & Kutter give the following table of safe bottom and mean velocity in channels, calculated from the formula  $v = v_b + 10.87 \sqrt{rs}$ :

Material of Channel.	Safe Bottom Velocity $v_b$ , in feet per second.	Mean Velocity $v$ , in feet per second.
Soft brown earth . . . . .	0.249	0.328
Soft loam . . . . .	0.499	0.656
Sand . . . . .	1.000	1.312
Gravel . . . . .	1.998	2.625
Pebbles . . . . .	2.999	3.938
Broken stone, flint . . . . .	4.003	5.579
Conglomerate, soft slate . . . . .	4.988	6.564
Stratified rock . . . . .	6.006	8.204
Hard rock . . . . .	10.009	13.127

Ganguillet & Kutter state that they are unable for want of observations to judge how far these figures are trustworthy. They consider them to be rather disproportionately small than too large, and therefore recommend them more confidently.

Water flowing at a high velocity and carrying large quantities of silt is very destructive to channels, even when constructed of the best masonry.

**Resistance of Soils to Erosion by Water.**—W. A. Burr, *Eng'g News*, Feb. 8, 1894, gives a diagram showing the resistance of various soils to erosion by flowing water.

Experiments show that a velocity greater than 1.1 feet per second will erode sand, while pure clay will stand a velocity of 7.35 feet per second. The greater the proportion of clay carried by any soil, the higher the permissible velocity. Mr. Burr states that experiments have shown that the line describing the power of soils to resist erosion is parabolic. From his diagram the following figures are selected representing different classes of soils:

Pure sand resists erosion by flow of . . . . .	1.1 feet per second.
Sandy soil, 15% clay . . . . .	1.2 " "
Sandy loam, 40% clay . . . . .	1.8 " "
Loamy soil, 65% clay . . . . .	3.0 " "
Clay loam, 85% clay . . . . .	4.8 " "
Agricultural clay, 95% clay . . . . .	6.2 " "
Clay . . . . .	7.35 " "

**Abrading and Transporting Power of Water.**—Prof. J. LeConte, in his "Elements of Geology," states:

The erosive power of water, or its power of overcoming cohesion, varies as the square of the velocity of the current.

The transporting power of a current varies as the sixth power of the velocity. \* \* \* If the velocity therefore be increased ten times, the transporting power is increased 1,000,000 times. A current running three feet per second, or about two miles per hour, will bear fragments of stone of the size of a hen's egg, or about three ounces weight. A current of ten miles an hour will bear fragments of one and a half tons, and a torrent of twenty miles an hour will carry fragments of 100 tons.

The transporting power of water must not be confounded with its erosive power. The resistance to be overcome in the one case is weight, in the other, cohesion; the latter varies as the square: the former as the sixth power of the velocity.

In many cases of removal of slightly cohering material, the resistance is a

mixture of these two resistances, and the power of removing material will vary at some rate between  $v^2$  and  $v^6$ .

Baldwin Latham has found that in order to prevent deposits of sewage silt in small sewers or drains, such as those from 6 inches to 9 inches diameter, a mean velocity of not less than 3 feet per second should be produced. Sewers from 12 to 24 inches diameter should have a velocity of not less than  $2\frac{1}{2}$  feet per second, and in sewers of larger dimensions in no case should the velocity be less than 2 feet per second.

The specific gravity of the materials has a marked effect upon the mean velocities necessary to move them. T. E. Blackwell found that coal of a sp. gr. of 1.26 was moved by a current of from 1.25 to 1.50 ft. per second, while stones of a sp. gr. of 2.32 to 3.00 required a velocity of 2.5 to 2.75 ft. per second.

Chailly gives the following formula for finding the velocity required to move rounded stones or shingle :

$$v = 5.67 \sqrt{ag},$$

in which  $v$  = velocity of water in feet per second.  $a$  = average diameter in feet of the body to be moved,  $g$  = its specific gravity.

Geo. Y. Wisner, *Eng'g News*, Jan 10, 1895, doubts the general accuracy of statements made by many authorities concerning the rate of flow of a current and the size of particles which different velocities will move. He says:

The scouring action of any river, for any given rate of current, must be an inverse function of the depth. The fact that some engineer has found that a given velocity of current on some stream of unknown depth will move sand or gravel has no bearing whatever on what may be expected of currents of the same velocity in streams of greater depths. In channels 3 to 5 ft. deep a mean velocity of 3 to 5 ft. per second may produce rapid scouring, while in depths of 18 ft. and upwards current velocities of 6 to 8 ft. per second often have no effect whatever on the channel bed.

**Grade of Sewers.**—The following empirical formula is given in Baumeister's "Cleaning and Sewerage of Cities," for the minimum grade for a sewer of clear diameter equal to  $d$  inches, and either circular or oval in section :

$$\text{Minimum grade, in per cent,} = \frac{100}{5d + 50}.$$

As the lowest limit of grades which can be flushed, 0.1 to 0.2 per cent may be assumed for sewers which are sometimes dry, while 0.3 per cent is allowable for the trunk sewers in large cities. The sewers should run dry as rarely as possible.

#### **Relation of Diameter of Pipe to Quantity Discharged.**—

In many cases which arise in practice the information sought is the diameter necessary to supply a given quantity of water under a given head. The diameter is commonly taken to vary as the two-fifth power of the discharge. This is almost certainly too large. Hagen's formula, with Prof.

Unwin's coefficients, give  $d = c \left( \frac{Q}{\left(\frac{h}{l}\right)^{\frac{1}{2}}} \right)^{.387}$ , where  $c = .239$  when  $d$  and  $Q$

are in feet and cubic feet per second.

Mr. Thrupp has proposed a formula which makes  $d$  vary as the .383 power of the discharge, and the formula of M. Vallot, a French engineer, makes  $d$  vary as the .375 power of the discharge. (*Engineering*.)

### **FLOW OF WATER—EXPERIMENTS AND TABLES.**

**The Flow of Water through New Cast-iron Pipe** was measured by S. Bent Russell, of the St. Louis, Mo., Water-works. The pipe was 12 inches in diameter, 1631 feet long, and laid on a uniform grade from end to end. Under an average total head of 3.36 feet the flow was 43,200 cubic feet in seven hours; under an average head of 3.37 feet the flow was the same; under an average total head of 3.41 feet the flow was 46,700 cubic feet in 8 hours and 35 minutes. Making allowance for loss of head due to entrance and to curves, it was found that the value of  $c$  in the formula  $v = c \sqrt{rs}$  was from 88 to 93. (*Eng'g Record*, April 14, 1894.)

**Flow of Water in a 20-inch Pipe 75,000 Feet Long.**—A comparison of experimental data with calculations by different formulæ is

given by Chas. B. Brush, Trans. A. S. C. E., 1888. The pipe experimented with was that supplying the city of Hoboken, N. J.

**RESULTS OBTAINED BY THE HACKENSACK WATER COMPANY, FROM 1882-1887. IN PUMPING THROUGH A 20-IN. CAST-IRON MAIN 75,000 FEET LONG.**

Pressure in lbs. per sq. in. at pumping-station:	95	100	105	110	115	120	125	130
Total effective head in feet:	55	66	77	89	100	112	122	135
Discharge in U. S. gallons in 24 hours, 1 = 1000 :	2,848	3,165	3,354	3,566	3,804	3,904	4,116	4,255
Actual velocity in main in feet per second :	2.00	2.24	2.36	2.52	2.68	2.76	2.92	3.00
Cost of coal consumed in delivering each million gals. at given velocities,	\$8.40	\$8.15	\$8.00	\$8.10	\$8.30	\$8.60	\$9.00	\$9.60
Theoretical discharge by D'Arcy's formula :	2,743	3,004	3,244	3,488	3,699	3,915	4,102	4,297

**Velocities in Smooth Cast-iron Water-pipes from 1 Foot to 9 Feet in Diameter, on Hydraulic Grades of 0.5 Foot to 8 Feet per Mile; with Corresponding Values of  $c$  in  $V = c \sqrt{rs}$ . (D. M. Greene, in *Eng'g News*, Feb. 24, 1894.)**

Diameters, feet. D.	Hydraulic Mean Radii. r.	Hydraulic Grade; Feet per Mile = $h$ .					
		$h = 0.5$ $s = 0.0000947$	1.0 0.0001894	1.5 0.0002841	2.0 0.0003788	3.0 0.0005632	4.0 0.0007576

		$c = 135.9$	141.4	146.0	146.8	150.2	152.5
8.	2.0	$V = 1.9218$	2.8234	3.5358	4.1479	5.1945	6.0936
		$c = 139.7$	145.1	148.4	150.7	154.1	156.5
9.	2.25	$V = 2.0854$	3.0638	3.8368	4.5010	5.6368	6.6125
		$c = 142.9$	148.4	151.7	154.2	157.6	160.1

The velocities in this table have been calculated by Mr. Greene's modification of the Chezy formula, which modification is found to give results which differ by from 1.29 to - 2.65 per cent (average 0.9 per cent) from very carefully measured flows in pipes from 16 to 48 inches in diameter, on grades from 1.68 feet to 10.296 feet per mile, and in which the velocities ranged from 1.577 to 6.195 feet per second. The only assumption made is that the modified formula for  $V$  gives correct results in conduits from 4 feet to 9 feet in diameter, as it is known to do in conduits less than 4 feet in diameter.

Other articles on Flow of Water in long tubes are to be found in *Eng'g News* as follows : G. B. Pearsons, Sept. 23, 1876; E. Sherman Gould, Feb. 16, 23, March 9, 16, and 23, 1889; J. L. Fitzgerald, Sept. 6 and 13, 1890; Jas. Duane, Jan. 2, 1892; J. T. Fanning, July 14, 1892; A. N. Talbot, Aug. 11, 1892.

For U. S. gallons multiply the figures in the table by 7.4805.

For a given diameter the quantity of flow varies as the square root of the sine of the slope. From this principle the flow for other slopes than those

given in the table may be found. Thus, what is the flow for a pipe 8 feet diameter, slope 1 in 125? From the table take  $Q = 207.3$  for slope 1 in 2000. The given slope 1 in 125 is to 1 in 2000 as 16 to 1, and the square root of this ratio is 4 to 1. Therefore the flow required is  $207.3 \times 4 = 829.2$  cu. ft.

**Circular Pipes, Conduits, etc., Flowing Full.**

Values of the factor  $ac\sqrt{r}$  in the formula  $Q = ac\sqrt{r} \times \sqrt{s}$  corresponding to different values of the coefficient of roughness,  $n$ . (Based on Kutter's formula.)

Diam. ft. in.	Value of $ac\sqrt{r}$ .					
	$n = .010.$	$n = .011.$	$n = .012.$	$n = .013.$	$n = .015.$	$n = .017.$

**Flow of Water in Circular Pipes, Conduits, etc., Flowing under Pressure.**

Based on D'Arcy's formulæ for the flow of water through cast-iron pipes. With comparison of results obtained by Kutter's formula, with  $n = .013$ . (Condensed from Flynn on Water Power.)

Values of  $a$ , and also the values of the factors  $c\sqrt{r}$  and  $ac\sqrt{r}$  for use in the formulæ  $Q = av$ ;  $v = c\sqrt{r} \times \sqrt{s}$ , and  $Q = ac\sqrt{r} \times \sqrt{s}$ .

$Q$  = discharge in cubic feet per second,  $a$  = area in square feet,  $v$  = velocity in feet per second,  $r$  = mean hydraulic depth,  $\frac{1}{4}$  diam. for pipes running full,  $s$  = sine of slope.

(For values of  $\sqrt{s}$  see page 558.)

Size of Pipe.		Clean Cast-iron Pipes.		Value of $ac\sqrt{r}$ by Kutter's Formula, when $n = .013$ .	Old Cast-iron Pipes Lined with Deposit.		
$d$ = diam. in ft. in.	$a$ = area in square feet.	For Velocity, $c\sqrt{r}$ .	For Discharge, $ac\sqrt{r}$ .		For Velocity, $c\sqrt{r}$ .	For Discharge, $ac\sqrt{r}$ .

For any other slope the flow is proportional to the square root of the slope ; thus, flow in slope of 1 in 100 is double that in slope of 1 in 400.

**Flow of Water in Pipes from  $\frac{3}{8}$  Inch to 12 Inches Diameter for a Uniform Velocity of 100 Ft. per Min.**

Given the diameter of a pipe, to find the quantity in gallons it will deliver, the velocity of flow being 100 ft. per minute. Square the diameter in inches and multiply by 4.08.

If  $Q'$  = quantity in gallons per minute and  $d$  = diameter in inches, then

$$Q' = \frac{d^2 \times .7854 \times 100 \times 7.4805}{144} = 4.08d^2.$$

For any other velocity,  $V'$ , in feet per minute,  $Q' = 4.08d^2 \frac{V'}{100} = .0408d^2 V'$ .

Given diameter of pipe in inches and velocity in feet per second, to find discharge in cubic feet and in gallons per minute.

$$Q' = \frac{d^2 \times .7854 \times v \times 60}{144} = 0.32725d^2v \text{ cubic feet per minute.}$$

$$= .32725 \times 7.4805 \text{ or } 2.448d^2v \text{ U. S. gallons per minute.}$$

To find the capacity of a pipe or cylinder in gallons, multiply the square of the diameter in inches by the length in inches and by .0034. Or multiply the square of the diameter in inches by the length in feet and by .0408.

$$Q = \frac{.7854d^2l}{231} = .0034d^2l \text{ (exact) } .0034 \times 12 = .0408.$$

**LOSS OF HEAD.**

The loss of head due to friction when water, steam, air, or gas of any kind flows through a straight tube is represented by the formula

$$h = f \frac{4l}{d} \frac{v^2}{2g}; \quad \text{whence } v = \sqrt{\frac{61.4}{4f} \frac{hd}{l}},$$

in which  $l$  = the length and  $d$  = the diameter of the tube, both in feet;  $v$  = velocity in feet per second, and  $f$  is a coefficient to be determined by experiment. According to Weisbach,  $f = .0064$ , in which case

$$\sqrt{\frac{61.4}{4f}} = 50, \text{ and } v = 50 \sqrt{\frac{hd}{l}},$$

which is one of the older formulæ for flow of water (Downing's). Prof. Unwin says that the value of  $f$  is possibly too small for tubes of small bore, and he would put  $f = .006$  to  $.01$  for 4-inch tubes, and  $f = .0084$  to  $.012$  for 2-inch tubes. Another formula by Weisbach is

$$h = \left( .0144 + \frac{.01716}{\sqrt{v}} \right) \frac{l}{d} \frac{v^2}{2g}.$$

Rankine gives

$$f = .005 \left( 1 + \frac{1}{12d} \right).$$

From the general equation for velocity of flow of water  $v = c \sqrt{r} \sqrt{s}$ , = for round pipes  $c \sqrt{\frac{d}{4}} \sqrt{\frac{h}{l}}$ , we have  $v^2 = c^2 \frac{d}{4} \frac{h}{l}$  and  $h = \frac{4lv^2}{c^2d}$ , in which

$c$  is the coefficient  $c$  of D'Arcy's, Bazin's, Kutter's, or other formula, as found by experiment. Since this coefficient varies with the condition of the inner surface of the tube, as well as with the velocity, it is to be expected that values of the loss of head given by different writers will vary as much as those of quantity of flow. Two tables for loss of head per 100 ft. in length in pipes of different diameters with different velocities are given below. The first is given by Clark, based on Ellis' and Howland's experiments; the second is from the Pelton Water-wheel Co.'s catalogue, based on Cox's formula, see p. 575, with the divisor 1000 instead of 1200, as it is for riveted steel pipe. The loss of head as given in these two tables for any given diameter and velocity differs considerably. Either table should be used with caution and the results compared with the quantity of flow for the given diameter and head as given in the tables of flow based on Kutter's and D'Arcy's formulæ.

**Relative Loss of Head by Friction for each 100 Feet Length of Clean Cast-iron Pipe.**

EXAMPLE.—Given 200 ft. head and 600 ft. of 11-inch pipe, carrying 119 cubic feet of water per minute. To find effective head: In right-hand column, under 11-inch pipe, find 119 cubic ft.; opposite this will be found the loss by friction in 100 ft. of length for this amount of water, which is .444. Multiply this by the number of hundred feet of pipe, which is 6, and we have 2.66 ft., which is the loss of head. Therefore the effective head is 200 - 2.66 = 197.34.

EXPLANATION.—The loss of head by friction in pipe depends not only upon diameter and length, but upon the quantity of water passed through it. The head or pressure is what would be indicated by a pressure-gauge attached to the pipe near the wheel. Readings of gauge should be taken while the water is flowing from the nozzle.

To reduce heads in feet to pressure in pounds multiply by .433. To reduce pounds pressure to feet multiply by 2.309.

**Cox's Formula.**—Weisbach's formula for loss of head caused by the friction of water in pipes is as follows:

$$\text{Friction-head} = \left( 0.0144 + \frac{0.01716}{\sqrt{V}} \right) \frac{L \cdot V^2}{5.367d}$$

where  $L$  = length of pipe in feet;

$V$  = velocity of the water in feet per second;

$d$  = diameter of pipe in inches.

William Cox (*Amer. Mach.*, Dec. 28, 1893) gives a simpler formula which gives almost identical results:

$$H = \text{friction-head in feet} = \frac{L}{d} \frac{4V^2 + 5V - 2}{1200} \dots \dots \dots (1)$$

$$\frac{Hd}{L} = \frac{4V^2 + 5V - 2}{1200} \dots \dots \dots (2)$$

He gives a table by means of which the value of  $\frac{4V^2 + 5V - 2}{1200}$  is at once obtained when  $V$  is known, and *vice versa*.

VALUES OF  $\frac{4V^2 + 5V - 2}{1200}$ .

The use of the formula and table is illustrated as follows:  
Given a pipe 5 inches diameter and 1000 feet long, with 49 feet head, what will the discharge be?

If the velocity  $V$  is known in feet per second, the discharge is  $0.32725d^2V$  cubic foot per minute.

By equation 2 we have

$$\frac{4V^2 + 5V - 2}{1200} = \frac{Hd}{L} = \frac{49 \times 5}{1000} = 0.245;$$

whence, by table,  $V$  = real velocity = 8 feet per second.

The discharge in cubic feet per minute, if  $V$  is velocity in feet per second and  $d$  diameter in inches, is  $0.32725d^2V$ , whence, discharge

$$= 0.32725 \times 25 \times 8 = 65.45 \text{ cubic feet per minute.}$$

The velocity due the head, if there were no friction, is  $8.025 \sqrt{H} = 56.175$  feet per second, and the discharge at that velocity would be

$$0.32725 \times 25 \times 56.175 = 460 \text{ cubic feet per minute.}$$

Suppose it is required to deliver this amount, 460 cubic feet, at a velocity of 2 feet per second, what diameter of pipe will be required and what will be the loss of head by friction?

$$d = \text{diameter} = \sqrt{\frac{Q}{V \times 0.32725}} = \sqrt{\frac{460}{2 \times 0.32725}} = \sqrt{703} = 26.5 \text{ inches.}$$

Having now the diameter, the velocity, and the discharge, the friction-head is calculated by equation 1 and use of the table; thus,

$$H = \frac{L}{d} \frac{4V^2 + 5V - 2}{1200} = \frac{1000}{26.5} \times 0.02 = \frac{20}{26.5} = 0.75 \text{ foot,}$$

thus leaving  $49 - 0.75 =$  say 48 feet effective head applicable to power-producing purposes.

Problems of the loss of head may be solved rapidly by means of Cox's Pipe Computer, a mechanical device on the principle of the slide-rule, for sale by Keuffel & Esser, New York.

**Frictional Heads at Given Rates of Discharge in Clean Cast-iron Pipes for Each 1000 Feet of Length.**

**Effect of Bends and Curves in Pipes.**—Weisbach's rule for bends: Loss of head in feet =  $\left[ .131 + 1.847 \left( \frac{r}{R} \right)^{\frac{7}{2}} \right] \times \frac{v^2}{64.4} \times \frac{a}{180}$ , in which  $r$  = internal radius of pipe in feet,  $R$  = radius of curvature of axis of pipe,  $v$  = velocity in feet per second, and  $a$  = the central angle, or angle subtended by the bend.

Hamilton Smith, Jr., in his work on Hydraulics, says: The experimental data at hand are entirely insufficient to permit a satisfactory analysis of this quite complicated subject; in fact, about the only experiments of value are those made by Bossut and Dubuat with small pipes.

**Curves.**—If the pipe has easy curves, say with radius not less than 5 diameters of the pipe, the flow will not be materially diminished, provided the tops of all curves are kept below the hydraulic grade-line and provision be made for escape of air from the tops of all curves. (Trautwine.)

**Hydraulic Grade-line.**—In a straight tube of uniform diameter throughout, running full and discharging freely into the air, the hydraulic grade-line is a straight line drawn from the discharge end to a point immediately over the entry end of the pipe and at a depth below the surface equal to the entry and velocity heads. (Trautwine.)

In a pipe leading from a reservoir, no part of its length should be above the hydraulic grade-line.

**Flow of Water in House-service Pipes.**

Mr. E. Kuichling, C.E., furnished the following table to the Thomson Meter Co.:

Condition of Discharge.	Pressure in Main, pounds per square inch.	Discharge, or Quantity capable of being delivered, in Cubic Feet per Minute, from the Pipe, under the conditions specified in the first column.								
		Nominal Diameters of Iron or Lead Service-pipe in Inches.								
		½	⅝	¾	1	1½	2	3	4	6
Through 35 feet of service-pipe, no back pressure.	30	1.10	1.92	3.01	6.13	16.58	33.34	88.16	173.85	444.63

	100	1.00	1.74	2.75	5.65	15.58	31.93	87.38	177.67	478.55
	130	1.15	2.02	3.19	6.55	18.07	37.02	101.33	206.04	554.96

In this table it is assumed that the pipe is straight and smooth inside; that the friction of the main and meter are disregarded; that the inlet from the main is of ordinary character, sharp, not flaring or rounded, and that the outlet is the full diameter of pipe. The deliveries given will be increased if, first, the pipe between the meter and the main is of larger diameter than the outlet; second, if the main is tapped, say for 1-inch pipe, but is enlarged from the tap to 1¼ or 1½ inch; or, third, if pipe on the outlet is larger than that on the inlet side of the meter. The exact details of the conditions given are rarely met in practice; consequently the quantities of the table may be expected to be decreased, because the pipe is liable to be throttled at the joints, additional bends may interpose, or stop-cocks may be used, or the back-pressure may be increased.

**Air-bound Pipes.**—A pipe is said to be air-bound when, in consequence of air being entrapped at the high points of vertical curves in the line, water will not flow out of the pipe, although the supply is higher than the outlet. The remedy is to provide cocks or valves at the high points, through which the air may be discharged. The valve may be made automatic by means of a float.

**Vertical Jets.** (Molesworth.)— $H$  = head of water,  $h$  = height of jet,  $d$  = diameter of jet,  $K$  = coefficient, varying with ratio of diameter of jet to head; then  $h = KH$ .

If $H = d \times$	300	600	1000	1500	1800	2800	3500	4500,
$K =$	.96	.9	.85	.8	.7	.6	.5	.25

**Water Delivered through Meters.** (Thomson Meter Co.).—The best modern practice limits the velocity in water-pipes to 10 lineal feet per second. Assume this as a basis of delivery, and we find, for the several sizes of pipes usually metered, the following approximate results:

Nominal diameter of pipe in inches:

	¾	⅝	¾	1	1½	2	3	4	6
Quantity delivered, in cubic feet per minute, due to said velocity:	0.46	1.28	1.85	3.28	7.36	13.1	29.5	52.4	117.9

**Prices Charged for Water in Different Cities** (National Meter Co.):

Average minimum price for 1000 gallons in 163 places.....	9.4 cents.
“ maximum “ “ “ “ “ “ “ .....	28 “
Extremes, 2½ cents to .....	100 “

FIRE-STREAMS.

**Friction Losses in Hose.**—In the above table the volumes of water discharged per jet were for stated pressures at the play-pipe.

In providing for this pressure due allowance is to be made for friction losses in each hose, according to the streams of greatest discharge which are to be used.

The loss of pressure or its equivalent loss of head ( $h$ ) in the hose may be found by the formula  $h = v^2(4m)\frac{l}{2gd}$ .

In this formula, as ordinarily used, for friction per 100 ft. of  $2\frac{1}{2}$ -in. hose there are the following constants:  $2\frac{1}{2}$  in. diameter of hose  $d = .20833$  ft.; length of hose  $l = 100$  ft., and  $2g = 64.4$ . The variables are:  $v =$  velocity in feet per second;  $h =$  loss of head in feet per 100 ft. of hose;  $m =$  a coefficient found by experiment; the velocity  $v$  is found from the given discharges of the jets through the given diameter of hose.

**Head and Pressure Losses by Friction in 100-ft. Lengths of Rubber-lined Smooth  $2\frac{1}{2}$ -in. Hose.**

Discharge per minute, gallons.	Velocity per second, ft.	Coefficient, $m$ .	Head Lost, ft.	Pressure Lost, lbs. per sq. in.	Gallons per 24 hours.
200	13.072	.00450	22.89	9.93	288,000
250	16.388	.00446	35.55	15.43	360,000
300	18.858	.00442	46.80	20.31	432,000
347	21.677	.00439	61.53	26.70	499,680
350	22.873	.00439	68.48	29.73	504,000
400	26.144	.00436	88.83	38.55	576,000
450	29.408	.00434	111.80	48.52	648,000
500	32.675	.00432	137.50	59.67	720,000
520	33.982	.00431	148.40	64.40	748,800

These frictions are for given volumes of flow in the hose and the velocities respectively due to those volumes, and are independent of size of nozzle. The changes in nozzle do not affect the friction in the hose if there is no change in velocity of flow, but a larger nozzle with equal pressure at the nozzle augments the discharge and velocity of flow, and thus materially increases the friction loss in the hose.

**Loss of Pressure ( $p$ ) and Head ( $h$ ) in Rubber-lined Smooth  $2\frac{1}{2}$ -in. Hose** may be found approximately by the formulæ

$p = \frac{lq^2}{4150d^5}$  and  $h = \frac{lq^2}{1801d^5}$ , in which  $p =$  pressure lost by friction, in pounds per square inch;  $l =$  length of hose in feet;  $q =$  gallons of water discharged per minute;  $d =$  diam. of the hose in inches,  $2\frac{1}{2}$  in.;  $h =$  friction-head in feet. The coefficient of  $d^5$  would be decreased for rougher hose.

The loss of pressure and head for a  $1\frac{1}{8}$ -in. stream with power to reach a height of 80 ft. is, in each 100 ft. of  $2\frac{1}{2}$ -in. hose, approximately 20 lbs., or 45 ft. net, or, say, including friction in the hydrant,  $\frac{1}{2}$  ft. loss of head for each foot of hose.

If we change the nozzles to  $1\frac{1}{4}$  or  $1\frac{3}{8}$  in. diameter, then for the same 80 ft. height of stream we increase the friction losses on the hose to approximately  $\frac{2}{3}$  ft. and 1 ft. head, respectively, for each foot-length of hose.

These computations show the great difficulty of maintaining a high stream through large nozzles unless the hose is very short, especially for a gravity or direct-pressure system.

This single  $1\frac{1}{8}$ -in. stream requires approximately 56 lbs pressure, equivalent to 129 ft. head, at the play-pipe, and 45 to 50 ft. head for each 100 ft. length of smooth  $2\frac{1}{2}$ -in. hose, so that for 100, 200, and 300 ft. of hose we must have available heads at the hydrant or fire-engine of 179, 229, and 279 ft., respectively. If we substitute  $1\frac{1}{4}$ -in. nozzles for same height of stream we must have available heads at the hydrants or engine of 193, 259, and 325 ft., respectively, or we must increase the diameter of a portion at least of the long hose and save friction-loss of head.

**Rated Capacities of Steam Fire-engines**, which is perhaps one third greater than their ordinary rate of work at fires, are substantially as follows:

3d size,	550 gals. per min., or	792,000 gals. per 24 hours.
2d "	700 " "	1,008,000 " "
1st "	900 " "	1,296,000 " "
1 ext.,	1,100 " "	1,584,000 " "

**Pressures required at Nozzle and at Pump, with Quantity and Pressure of Water Necessary to throw Water Various Distances through Different-sized Nozzles—using 2½-inch Rubber Hose and Smooth Nozzles.**

(From Experiments of Ellis & Leshure, Fanning's "Water Supply.")

Size of Nozzles.	1 Inch.				1½ Inch.			
	40	60	80	100	40	60	80	100
Pressure at nozzle, lbs. per sq. in.....	40	60	80	100	40	60	80	100
* Pressure at pump or hydrant with 100 ft. 2½-inch rubber hose.....	48	73	97	121	54	81	108	135
Gallons per minute. ....	155	189	219	245	196	240	277	310
Horizontal distance thrown, feet.....	109	142	168	186	113	148	175	193
Vertical distance thrown, feet.....	79	108	131	148	81	112	137	157

Size of Nozzles.	1¼ Inch.				1¾ Inch.			
	40	60	80	100	40	60	80	100
Pressure at nozzle, lbs. per sq. in.....	40	60	80	100	40	60	80	100
* Pressure at pump or hydrant with 100 feet 2½-inch rubber hose.....	61	92	123	154	71	107	144	180
Gallons per minute... ..	242	297	342	383	293	358	413	462
Horizontal distance thrown, feet.....	118	156	186	207	124	166	200	224
Vertical distance thrown, feet.....	82	115	142	164	85	118	146	169

\* For greater length of 2½-inch hose the increased friction can be obtained by noting the differences between the above given "pressure at nozzle" and "pressure at pump or hydrant with 100 feet of hose." For instance, if it requires at hydrant or pump eight pounds more pressure than it does at nozzle to overcome the friction when pumping through 100 feet of 2½-inch hose (using 1-inch nozzle, with 40-pound pressure at said nozzle) then it requires 16-pounds pressure to overcome the friction in forcing through 200 feet of same size hose.

**Decrease of Flow due to Increase of Length of Hose.** (J. R. Freeman's Experiments, Trans. A. S. C. E. 1889.)—If the static pressure is 80 lbs. and the hydrant-pipes of such size that the pressure at the hydrant is 70 lbs., the hose 2½ in. nominal diam., and the nozzle 1½ in. diam., the height of effective fire-stream obtainable and the quantity in gallons per minute will be:

	Linen Hose.		Best Rubber-lined Hose.	
	Height, feet.	Gals. per min.	Height, feet.	Gals. per min.
With 50 ft. of 2½-in. hose.....	73	261	81	282
" 250 " " " " .....	42	184	61	229
" 500 " " " " .....	27	146	46	192

With 500 ft. of smoothest and best rubber-lined hose, if diameter be exactly 2½ in., effective height of stream will be 39 ft. (177 gals.); if diameter be ½ in. larger, effective height of stream will be 46 ft. (192 gals.)

**THE SIPHON.**

The Siphon is a bent tube of unequal branches,"open at both ends, and is used to convey a liquid from a higher to a lower level, over an intermediate point higher than either. Its parallel branches being in a vertical plane and plunged into two bodies of liquid whose upper surfaces are at different levels, the fluid will stand at the same level both within and without each branch of the tube when a vent or small opening is made at the bend. If the air be withdrawn from the siphon through this vent, the water will rise in the branches by the atmospheric pressure without, and when the two columns unite and the vent is closed, the liquid will flow from the upper reservoir as long as the end of the shorter branch of the siphon is below the surface of the liquid in the reservoir.

If the water was free from air the height of the bend above the supply level might be as great as 33 feet.

If  $A$  = area of cross-section of the tube in square feet,  $H$  = the difference in level between the two reservoirs in feet,  $D$  the density of the liquid in pounds per cubic foot, then  $ADH$  measures the intensity of the force which causes the movement of the fluid, and  $V = \sqrt{2gH} = 8.02 \sqrt{H}$  is the theoretical velocity, in feet per second, which is reduced by the loss of head for entry and friction, as in other cases of flow of liquids through pipes. In the case of the difference of level being greater than 33 feet, however, the velocity of the water in the shorter leg is limited to that due to a height of 33 feet, or that due to the difference between the atmospheric pressure at the entrance and the vacuum at the bend.

Leicester Allen (*Am. Mach.*, Nov. 2, 1893) says: The supply of liquid to a siphon must be greater than the flow which would take place from the discharge end of the pipe, provided the pipe were filled with the liquid, the supply end stopped, and the discharge end opened when the discharge end is left free, unregulated, and unsubmerged.

To illustrate this principle, let us suppose the extreme case of a siphon having a calibre of 1 foot, in which the difference of level, or between the point of supply and discharge, is 4 inches. Let us further suppose this siphon to be at the sea-level, and its highest point above the level of the supply to be 27 feet. Also suppose the discharge end of this siphon to be unregulated, unsubmerged. It would be inoperative because the water in the longer leg would not be held solid by the pressure of the atmosphere against it, and it would therefore break up and run out faster than it could be replaced at the inflow end under an effective head of only 4 inches.

**Long Siphons.**—Prof. Joseph Torrey, in the *Amer. Machinist*, describes a long siphon which was a partial failure.

The length of the pipe was 1792 feet. The pipe was 3 inches diameter, and rose at one point 9 feet above the initial level. The final level was 20 feet below the initial level. No automatic air valve was provided. The highest point in the siphon was about one third the total distance from the pond and nearest the pond. At this point a pump was placed, whose mission was to fill the pipe when necessary. This siphon would flow for about two hours and then cease, owing to accumulation of air in the pipe. When in full operation it discharged  $43\frac{1}{2}$  gallons per minute. The theoretical discharge from such a sized pipe with the specified head is  $55\frac{1}{2}$  gallons per minute.

**Siphon on the Water-supply of Mount Vernon, N. Y.** (*Eng'g News*, May 4, 1893.)—A 12-inch siphon, 925 feet long, with a maximum lift of 22.12 feet and a  $45^\circ$  change in alignment, was put in use in 1893 by the New York City Suburban Water Co., which supplies Mount Vernon, N. Y.

At its summit the siphon crosses a supply main, which is tapped to charge the siphon.

The air-chamber at the siphon is 12 inches by 16 feet long. A  $\frac{1}{2}$ -inch tap and cock at the top of the chamber provide an outlet for the collected air.

It was found that the siphon with air-chamber as described would run until 125 cubic feet of air had gathered, and that this took place only half as soon with a 14-foot lift as with the full lift of 22.12 feet. The siphon will operate about 12 hours without being recharged, but more water can be gotten over by charging every six hours. It can be kept running 23 hours out of 24 with only one man in attendance. With the siphon as described above it is necessary to close the valves at each end of the siphon to recharge it.

It has been found by weir measurements that the discharge of the siphon before air accumulates at the summit is practically the same as through a straight pipe.

## MEASUREMENT OF FLOWING WATER.

**Piezometer.**—If a vertical or oblique tube be inserted into a pipe containing water under pressure, the water will rise in the former, and the vertical height to which it rises will be the head producing the pressure at the point where the tube is attached. Such a tube is called a piezometer or pressure measure. If the water in the piezometer falls below its proper level it shows that the pressure in the main pipe has been reduced by an obstruction between the piezometer and the reservoir. If the water rises above its proper level, it indicates that the pressure there has been increased by an obstruction beyond the piezometer.

If we imagine a pipe full of water to be provided with a number of piezometers, then a line joining the tops of the columns of water in them is the hydraulic grade-line.

**Pitot Tube Gauge.**—The Pitot tube is used for measuring the velocity of fluids in motion. It has been used with great success in measuring the flow of natural gas. (S. W. Robinson, Report Ohio Geol. Survey, 1890.) (See also *Van Nostrand's Mag.*, vol. xxxv.) It is simply a tube so bent that a short leg extends into the current of fluid flowing from a tube, with the plane of the entering orifice opposed at right angles to the direction of the current. The pressure caused by the impact of the current is transmitted through the tube to a pressure-gauge of any kind, such as a column of water or of mercury, or a Bourdon spring-gauge. From the pressure thus indicated and the known density and temperature of the flowing gas is obtained the head corresponding to the pressure, and from this the velocity. In a modification of the Pitot tube described by Prof. Robinson, there are two tubes inserted into the pipe conveying the gas, one of which has the plane of the orifice at right angles to the current, to receive the static pressure plus the pressure due to impact; the other has the plane of its orifice parallel to the current, so as to receive the static pressure only. These tubes are connected to the legs of a *U* tube partly filled with mercury, which then registers the difference in pressure in the two tubes, from which the velocity may be calculated. Comparative tests of Pitot tubes with gas-meters, for measurement of the flow of natural gas, have shown an agreement within 3%.

**The Venturi Meter**, invented by Clemens Herschel, and described in a pamphlet issued by the Builders' Iron Foundry of Providence, R. I., is named from Venturi, who first called attention, in 1796, to the relation between the velocities and pressures of fluids when flowing through converging and diverging tubes.

It consists of two parts—the tube, through which the water flows, and the recorder, which registers the quantity of water that passes through the tube.

The tube takes the shape of two truncated cones joined in their smallest diameters by a short throat-piece. At the up-stream end and at the throat there are pressure-chambers, at which points the pressures are taken.

The action of the tube is based on that property which causes the small section of a gently expanding frustum of a cone to receive, without material resultant loss of head, as much water at the smallest diameter as is discharged at the large end, and on that further property which causes the pressure of the water flowing through the throat to be less, by virtue of its greater velocity, than the pressure at the up-stream end of the tube, each pressure being at the same time a function of the velocity at that point and of the hydrostatic pressure which would obtain were the water motionless within the pipe.

The recorder is connected with the tube by pressure-pipes which lead to it from the chambers surrounding the up-stream end and the throat of the tube. It may be placed in any convenient position within 1000 feet of the tube. It is operated by a weight and clockwork.

The difference of pressure or head at the entrance and at the throat of the meter is balanced in the recorder by the difference of level in two columns of mercury in cylindrical receivers, one within the other. The inner carries a float, the position of which is indicative of the quantity of water flowing through the tube. By its rise and fall the float varies the time of contact between an integrating drum and the counters by which the successive readings are registered.

There is no limit to the sizes of the meters nor the quantity of water that may be measured. Meters with 24-inch, 36-inch, 48-inch, and even 20-foot tubes can be readily made.

**Measurement by Venturi Tubes.** (Trans. A. S. C. E., Nov., 1887, and Jan., 1888.)—Mr. Herschel recommends the use of a Venturi tube, inserted in the force-main of the pumping-engine, for determining the quantity of water discharged. Such a tube applied to a 24-inch main has a total length of about 20 feet. At a distance of 4 feet from the end nearest the engine the inside diameter of the tube is contracted to a throat having a diameter of about 8 inches. A pressure-gauge is attached to each of two chambers, the one surrounding and communicating with the entrance or main pipe, the other with the throat. According to experiments made upon two tubes of this kind, one 4 in. in diameter at the throat and 12 in. at the entrance, and the other about 36 in. in diameter at the throat and 9 feet at its entrance, the quantity of water which passes through the tube is very nearly the theoretical discharge through an opening having an area equal to that of the throat, and a velocity which is that due to the difference in head shown

by the two gauges. Mr. Herschel states that the coefficient for these two widely-varying sizes of tubes and for a wide range of velocity through the pipe, was found to be within two per cent. either way, of 98%. In other words, the quantity of water flowing through the tube per second is expressed within two per cent by the formula  $W = 0.98 \times A \times \sqrt{2gh}$ , in which  $A$  is the area of the throat of the tube,  $h$  the head, in feet, corresponding to the difference in the pressure of the water entering the tube and that found at the throat, and  $g = 32.16$ .

**Measurement of Discharge of Pumping-engines by Means of Nozzles.** (Trans. A. S. M. E., xii. 575).—The measurement of water by computation from its discharge through orifices, or through the nozzles of fire-hose, furnishes a means of determining the quantity of water delivered by a pumping-engine which can be applied without much difficulty. John R. Freeman, Trans. A. S. C. E., Nov., 1889, describes a series of experiments covering a wide range of pressures and sizes, and the results showed that the coefficient of discharge for a smooth nozzle of ordinary good form was within one half of one per cent, either way, of 0.977; the diameter of the nozzle being accurately calipered, and the pressures being determined by means of an accurate gauge attached to a suitable piezometer at the base of the play-pipe.

In order to use this method for determining the quantity of water discharged by a pumping-engine, it would be necessary to provide a pressure-box, to which the water would be conducted, and attach to the box as many nozzles as would be required to carry off the water. According to Mr. Freeman's estimate, four 1¼-inch nozzles, thus connected, with a pressure of 80 lbs. per square inch, would discharge the full capacity of a two-and-a-half-million engine. He also suggests the use of a portable apparatus with a single opening for discharge, consisting essentially of a Siamese nozzle, so-called, the water being carried to it by three or more lines of fire-hose.

To insure reliability for these measurements, it is necessary that the shut-off valve in the force-main, or the several shut-off valves, should be tight, so that all the water discharged by the engine may pass through the nozzles.

**Flow through Rectangular Orifices.** (Approximate. See p. 556.)

CUBIC FEET OF WATER DISCHARGED PER MINUTE THROUGH AN ORIFICE ONE INCH SQUARE, UNDER ANY HEAD OF WATER FROM 3 TO 72 INCHES.

For any other orifice multiply by its area in square inches.

Formula,  $Q' = .624 \sqrt{h'} \times a$ .  $Q'$  = cu. ft. per min.;  $a$  = area in sq. in.

**Measurement of an Open Stream by Velocity and Cross-section.**—Measure the depth of the water at from 6 to 12 points across the stream at equal distances between. Add all the depths in feet together and divide by the number of measurements made; this will be the average depth of the stream, which multiplied by its width will give its area or cross-section. Multiply this by the velocity of the stream in feet per minute, and the result will be the discharge in cubic feet per minute of the stream.

The velocity of the stream can be found by laying off 100 feet of the bank and throwing a float into the middle, noting the time taken in passing over the 100 ft. Do this a number of times and take the average; then, dividing

this distance by the time gives the velocity at the surface. As the top of the stream flows faster than the bottom or sides—the average velocity being about 83% of the surface velocity at the middle—it is convenient to measure a distance of 120 feet for the float and reckon it as 100.

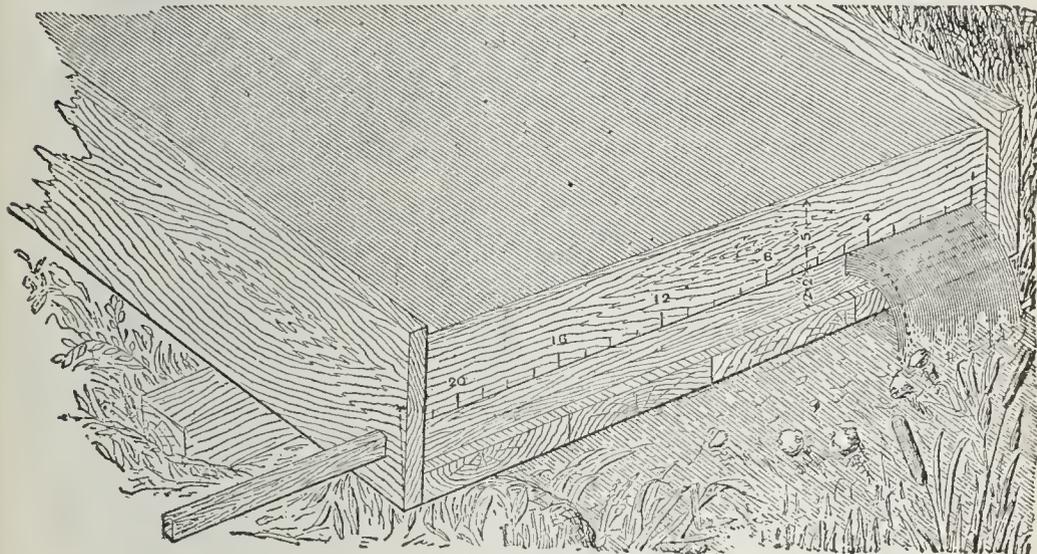

FIG. 130.

**Miners' Inch Measurements.** (Pelton Water Wheel Co.)

The cut, Fig. 130, shows the form of measuring-box ordinarily used, and the following table gives the discharge in cubic feet per minute of a miner's inch of water, as measured under the various heads and different lengths and heights of apertures used in California.

Length of Opening in inches.	Openings 2 Inches High.			Openings 4 Inches High.		
	Head to Centre, 5 inches.	Head to Centre, 6 inches.	Head to Centre, 7 inches.	Head to Centre, 5 inches.	Head to Centre, 6 inches.	Head to Centre, 7 inches.
	Cu. ft.					
4	1.348	1.473	1.589	1.320	1.450	1.570

80	1.368	1.493	1.609	1.366	1.509	1.641
90	1.369	1.493	1.610	1.366	1.509	1.641
100	1.369	1.494	1.610	1.366	1.509	1.642

NOTE.—The apertures from which the above measurements were obtained

were through material  $1\frac{1}{4}$  inches thick, and the lower edge 2 inches above the bottom of the measuring-box, thus giving full contraction.

**Flow of Water Over Weirs. Weir Dam Measurement.** (Pelton Water Wheel Co.)—Place a board or plank in the stream, as shown

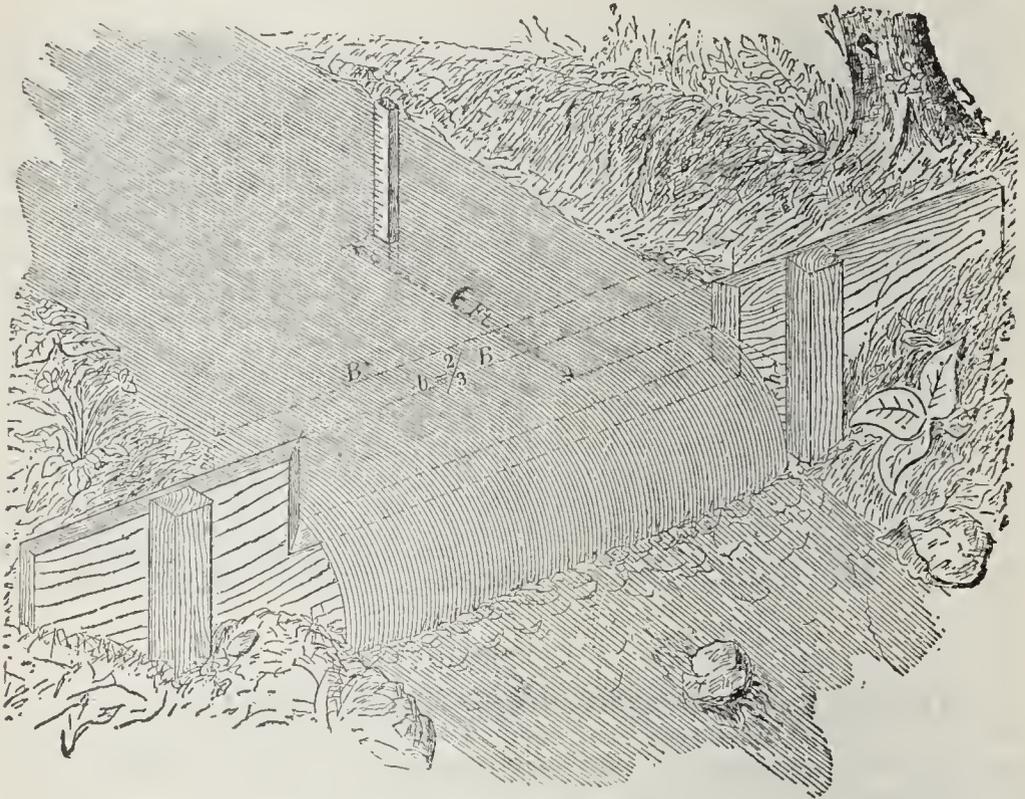

FIG. 131.

in the sketch, at some point where a pond will form above. The length of the notch in the dam should be from two to four times its depth for small quantities and longer for large quantities. The edges of the notch should be bevelled toward the intake side, as shown. The overfall below the notch should not be less than twice its depth. [Francis says a fall below the crest equal to one-half the head is sufficient, but there must be a free access of air under the sheet.]

In the pond, about 6 ft. above the dam, drive a stake, and then obstruct the water until it rises precisely to the bottom of the notch and mark the stake at this level. Then complete the dam so as to cause all the water to flow through the notch, and, after time for the water to settle, mark the stake again for this new level. If preferred the stake can be driven with its top precisely level with the bottom of the notch and the depth of the water be measured with a rule after the water is flowing free, but the marks are preferable in most cases. The stake can then be withdrawn; and the distance between the marks is the theoretical depth of flow corresponding to the quantities in the table on the following page.

**Francis's Formulæ for Weirs.**

	As given by Francis.	As modified by Smith.
Weirs with both end contractions } suppressed . . . . . }	$Q = 3.33lh^{\frac{3}{2}}$	$3.29\left(l + \frac{h}{7}\right)h^{\frac{3}{2}}$
Weirs with one end contraction } suppressed . . . . . }	$Q = 3.33(l - .1h)h^{\frac{3}{2}}$	$3.29lh^{\frac{3}{2}}$
Weirs with full contraction . . . . .	$Q = 3.33(l - .2h)h^{\frac{3}{2}}$	$3.29\left(l - \frac{h}{10}\right)h^{\frac{3}{2}}$

The greatest variation of the Francis formulæ from the values of *c* given by Smith amounts to 3½%. The modified Francis formulæ, says Smith, will give results sufficiently exact, when great accuracy is not required, within the limits of *h*, from .5 ft. to 2 ft., *l* being not less than 3 *h*.

$Q$  = discharge in cubic feet per second,  $l$  = length of weir in feet,  $h$  = effective head in feet, measured from the level of the crest to the level of still water above the weir.

If  $Q'$  = discharge in cubic feet per minute, and  $l'$  and  $h'$  are taken in inches, the first of the above formulæ reduces to  $Q' = 0.4l'h'^{\frac{3}{2}}$ . From this formula the following table is calculated. The values are sufficiently accurate for ordinary computations of water-power for weirs without end contraction, that is, for a weir the full width of the channel of approach, and are approximate also for weirs with end contraction when  $l =$  at least  $10h$ , but about 6% in excess of the truth when  $l = 4h$ .

**Weir Table.**

GIVING CUBIC FEET OF WATER PER MINUTE THAT WILL FLOW OVER A WEIR ONE INCH WIDE AND FROM  $\frac{1}{8}$  TO  $20\frac{7}{8}$  INCHES DEEP.

For other widths multiply by the width in inches.

	$\frac{1}{8}$ in.	$\frac{1}{4}$ in.	$\frac{3}{8}$ in.	$\frac{1}{2}$ in.	$\frac{5}{8}$ in.	$\frac{3}{4}$ in.	$\frac{7}{8}$ in.

For more accurate computations, the coefficients of flow of Hamilton Smith, Jr., or of Bazin should be used. In Smith's hydraulics will be found a collection of results of experiments on orifices and weirs of various shapes made by many different authorities, together with a discussion of their several formulæ. (See also Trautwine's Pocket Book.)

**Bazin's Experiments.**—M. Bazin (*Annales des Ponts et Chaussées*, Oct., 1888, translated by Marichal and Trautwine, Proc. Engrs. Club of Phila., Jan., 1890), made an extensive series of experiments with a sharp-crested weir without lateral contraction, the air being admitted freely behind the falling sheet, and found values of  $m$  varying from 0.42 to 0.50, with variations of the length of the weir from  $19\frac{3}{4}$  to  $78\frac{3}{4}$  in., of the height of the crest above the bottom of the channel from 0.79 to 2.46 ft., and of the head from 1.97 to 23.62 in. From these experiments he deduces the following formula :

$$Q = \left[ 0.425 + 0.21 \left( \frac{H}{P + H} \right)^2 \right] LH \sqrt{2gH},$$

in which  $P$  is the height in feet of the crest of the weir above the bottom of the channel of approach,  $L$  the length of the weir,  $H$  the head, both in feet, and  $Q$  the discharge in cu. ft. per sec. This formula, says M. Bazin, is entirely practical where errors of 2% to 3% are admissible. The following table is condensed from M. Bazin's paper :

VALUES OF THE COEFFICIENT  $m$  IN THE FORMULA  $Q = mLH \sqrt{2gH}$ , FOR A SHARP-CRESTED WEIR WITHOUT LATERAL CONTRACTION; THE AIR BEING ADMITTED FREELY BEHIND THE FALLING SHEET.

A comparison of the results of this formula with those of experiments, says M. Bazin, justifies us in believing that, except in the unusual case of a very low weir (which should always be avoided), the preceding table will give the coefficient  $m$  in all cases within 1%; provided, however, that the arrangements of the standard weir are exactly reproduced. It is especially important that the admission of the air behind the falling sheet be perfectly assured. If this condition is not complied with,  $m$  may vary within much wider limits. The type adopted gives the least possible variation in the coefficient.

WATER-POWER.

**Power of a Fall of Water—Efficiency.**—The gross power of a fall of water is the product of the weight of water discharged in a unit of time into the total head, i.e., the difference of vertical elevation of the upper surface of the water at the points where the fall in question begins and ends. The term "head" used in connection with water-wheels is the difference in height from the surface of the water in the wheel-pit to the surface in the pen-stock when the wheel is running.

If  $Q$  = cubic feet of water discharged per second,  $D$  = weight of a cubic foot of water = 62.36 lbs. at 60° F.,  $H$  = total head in feet; then

$DQH$  = gross power in foot-pounds per second,  
and  $DQH \div 550 = .1134QH$  = gross horse-power.

If  $Q'$  is taken in cubic feet per minute, H. P. =  $\frac{Q'H \times 62.36}{33,000} = .00189Q'H$ .

A water-wheel or motor of any kind cannot utilize the whole of the head  $H$ , since there are losses of head at both the entrance to and the exit from the wheel. There are also losses of energy due to friction of the water in its passage through the wheel. The ratio of the power developed by the wheel to the gross power of the fall is the efficiency of the wheel. For 75%

efficiency, net horse-power =  $.00142Q'H = \frac{Q'H}{705}$ .

A head of water can be made use of in one or other of the following ways viz. :

- 1st. By its weight, as in the water-balance and overshot-wheel.
- 2d. By its pressure, as in turbines and in the hydraulic engine, hydraulic press, crane, etc.
- 3d. By its impulse, as in the undershot-wheel, and in the Pelton wheel.
- 4th. By a combination of the above.

**Horse-power of a Running Stream.**—The gross horse-power is,  $H. P. = QH \times 62.36 \div 550 = .1134QH$ , in which  $Q$  is the discharge in cubic feet per second actually impinging on the float or bucket, and  $H$  = theoretical head due to the velocity of the stream  $= \frac{v^2}{2g} = \frac{v^2}{64.4}$ , in which  $v$  is the velocity in feet per second. If  $Q'$  be taken in cubic feet per minute,  $H. P. = .00189Q'H$ .

Thus, if the floats of an undershot-wheel driven by a current alone be 5 feet  $\times$  1 foot, and the velocity of stream = 210 ft. per minute, or  $3\frac{1}{2}$  ft. per sec., of which the theoretical head is .19 ft.,  $Q = 5$  sq. ft.  $\times$  210 = 1050 cu. ft. per minute;  $H = .19$  ft.;  $H. P. = 1050 \times .19 \times .00189 = .377$  H. P.

The wheels would realize only about .4 of this power, on account of friction and slip, or .151 H. P., or about .03 H. P. per square foot of float, which is equivalent to 33 sq. ft. of float per H. P.

**Current Motors.**—A current motor could only utilize the whole power of a running stream if it could take all the velocity out of the water, so that it would leave the floats or buckets with no velocity at all; or in other words, it would require the backing up of the whole volume of the stream until the actual head was equivalent to the theoretical head due to the velocity of the stream. As but a small fraction of the velocity of the stream can be taken up by a current motor, its efficiency is very small. Current motors may be used to obtain small amounts of power from large streams, but for large powers they are not practicable.

**Horse-power of Water Flowing in a Tube.**—The head due to the velocity is  $\frac{v^2}{2g}$ ; the head due to the pressure is  $\frac{f}{w}$ ; the head due to actual height above the datum plane is  $h$  feet. The total head is the sum of these =  $\frac{v^2}{2g} + h + \frac{f}{w}$ , in feet, in which  $v$  = velocity in feet per second,  $f$  = pressure in lbs. per sq. ft.,  $w$  = weight of 1 cu. ft. of water = 62.36 lbs. If  $p$  = pressure in lbs. per sq. in.,  $\frac{f}{w} = 2.309p$ . In hydraulic transmission the velocity and the height above datum are usually small compared with the pressure-head. The work or energy of a given quantity of water under pressure = its volume in cubic feet  $\times$  its pressure in lbs. per sq. ft.; or if  $Q$  = quantity in cubic feet per second, and  $p$  = pressure in lbs. per square inch,  $W = 144pQ$ , and the  $H. P. = \frac{144pQ}{550} = .2618pQ$ .

**Maximum Efficiency of a Long Conduit.**—A. L. Adams and R. C. Gemmell (*Eng'g News*, May 4, 1893), show by mathematical analysis that the conditions for securing the maximum amount of power through a long conduit of fixed diameter, without regard to the economy of water, is that the draught from the pipe should be such that the frictional loss in the pipe will be equal to one third of the entire static head.

**Mill-Power.**—A "mill-power" is a unit used to rate a water-power for the purpose of renting it. The value of the unit is different in different localities. The following are examples (from Emerson):

*Holyoke, Mass.*—Each mill-power at the respective falls is declared to be the right during 16 hours in a day to draw 38 cu. ft. of water per second at the upper fall when the head there is 20 feet, or a quantity proportionate to the height at the falls. This is equal to 86.2 horse-power as a maximum.

*Lowell, Mass.*—The right to draw during 15 hours in the day so much water as shall give a power equal to 25 cu. ft. a second at the great fall, when the fall there is 30 feet. Equal to 85 H. P. maximum.

*Lawrence, Mass.*—The right to draw during 16 hours in a day so much water as shall give a power equal to 30 cu. ft. per second when the head is 25 feet. Equal to 85 H. P. maximum.

*Minneapolis, Minn.*—30 cu. ft. of water per second with head of 22 feet. Equal to 74.8 H. P.

*Manchester, N. H.*—Divide 725 by the number of feet of fall minus 1, and

the quotient will be the number of cubic feet per second in that fall. For 20 feet fall this equals 38.1 cu. ft., equal to 86.4 H. P. maximum.

*Cohoes, N. Y.*—"Mill-power" equivalent to the power given by 6 cu. ft. per second, when the fall is 20 feet. Equal to 13.6 H. P., maximum.

*Passaic, N. J.*—Mill-power: The right to draw  $8\frac{1}{2}$  cu. ft. of water per sec., fall of 22 feet, equal to 21.2 horse-power. Maximum rental \$700 per year for each mill-power = \$33.00 per H. P.

The horse-power maximum above given is that due theoretically to the weight of water and the height of the fall, assuming the water-wheel to have perfect efficiency. It should be multiplied by the efficiency of the wheel, say 75% for good turbines, to obtain the H. P. delivered by the wheel.

**Value of a Water-power.**—In estimating the value of a water-power, especially where such value is used as testimony for a plaintiff whose water-power has been diminished or confiscated, it is a common custom for the person making such estimate to say that the value is represented by a sum of money which, when put at interest, would maintain a steam-plant of the same power in the same place.

Mr. Charles T. Main (Trans. A. S. M. E. xiii, 140) points out that this system of estimating is erroneous; that the value of a power depends upon a great number of conditions, such as location, quantity of water, fall or head, uniformity of flow, conditions which fix the expense of dams, canals, foundations of buildings, freight charges for fuel, raw materials and finished product, etc. He gives an estimate of relative cost of steam and water-power for a 500 H. P. plant from which the following is condensed:

The amount of heat required per H. P. varies with different kinds of business, but in an average plain cotton-mill, the steam required for heating and slashing is equivalent to about 25% of steam exhausted from the high-pressure cylinder of a compound engine of the power required to run that mill, the steam to be taken from the receiver.

The coal consumption per H. P. per hour for a compound engine is taken at  $1\frac{3}{4}$  lbs. per hour, when no steam is taken from the receiver for heating purposes. The gross consumption when 25% is taken from the receiver is about 2.06 lbs.

75% of the steam is used as in a compound engine at 1.75 lbs. = 1.31 lbs.  
 25% " " " " high-pressure " 3.00 lbs. = .75 "

2.06 "

The running expenses per H. P. per year are as follows :

2.06 lbs. coal per hour = 21.15 lbs. for $10\frac{1}{4}$ hours or one day = 6503.42	
lbs. for 308 days, which, at \$3.00 per long ton =	\$8 71
Attendance of boilers, one man @ \$2.00, and one man @ \$1.25 =	2 00
" " engine, " " " \$3.50.	2 16
	80

Oil, waste, and supplies.

The cost of such a steam-plant in New England and vicinity of 500 H. P. is about \$65 per H. P. Taking the fixed expenses as 4% on engine, 5% on boilers, and 2% on other portions, repairs at 2%, interest at 5%, taxes at  $1\frac{1}{2}$ % on  $\frac{3}{4}$  cost, an insurance at  $\frac{1}{2}$ % on exposed portion, the total average per cent is about  $12\frac{1}{2}$ %, or  $\$65 \times .12\frac{1}{2} =$  8 13

Gross cost of power and low-pressure steam per H. P. \$21 80

Comparing this with water-power, Mr. Main says: "At Lawrence the cost of dam and canals was about \$650,000, or \$65 per H. P. The cost per H. P. of wheel-plant from canal to river is about \$45 per H. P. of plant, or about \$65 per H. P. used, the additional \$20 being caused by making the plant large enough to compensate for fluctuation of power due to rise and fall of river. The total cost per H. P. of developed plant is then about \$130 per H. P. Placing the depreciation on the whole plant at 2%, repairs at 1%, interest at 5%, taxes and insurance at 1%, or a total of 9%, gives:

Fixed expenses per H. P. $\$130 \times .09 =$	\$11 70
Running " " " (Estimated)	2 00
	<u>\$13 70</u>

"To this has to be added the amount of steam required for heating purposes, said to be about 25% of the total amount used, but in winter months the consumption is at least  $37\frac{1}{2}$ %. It is therefore necessary to have a boiler plant of about  $37\frac{1}{2}$ % of the size of the one considered with the steam-plant,

costing about  $\$20 \times .375 = \$7.50$  per H. P. of total power used. The expense of running this boiler-plant is, per H. P. of the the total plant per year:

Fixed expenses $12\frac{1}{2}\%$ on $\$7.50$ ,.....	\$0.94
Coal.....	3.26
Labor.....	1.23
	\$5.43
Total .....	\$5.43

Making a total cost per year for water-power, with the auxiliary boiler plant  $\$13.70 + \$5.43 = \$19.13$  which deducted from  $\$21.80$  make a difference in favor of water-power of  $\$2.67$ , or for 10,000 H. P. a saving of  $\$26,700$  per year.

“It is fair to say,” says Mr. Main, “that the value of this constant power is a sum of money which when put at interest will produce the saving; or if 6% is a fair interest to receive on money thus invested the value would be  $\$26,700 \div .06 = \$445,000$ .”

Mr. Main makes the following general statements as to the value of a water-power: “The value of an undeveloped variable power is usually nothing if its variation is great, unless it is to be supplemented by a steam-plant. It is of value then only when the cost per horse-power for the double-plant is less than the cost of steam-power under the same conditions as mentioned for a permanent power, and its value can be represented in the same manner as the value of a permanent power has been represented.

“The value of a developed power is as follows: If the power can be run cheaper than steam, the value is that of the power, plus the cost of plant, less depreciation. If it cannot be run as cheaply as steam, considering its cost, etc., the value of the power itself is nothing, but the value of the plant is such as could be paid for it new, which would bring the total cost of running down to the cost of steam-power, less depreciation.”

Mr. Samuel Webber, *Iron Age*, Feb. and March, 1893, writes a series of articles showing the development of American turbine wheels, and incidentally criticises the statements of Mr. Main and others who have made comparisons of costs of steam and of water-power unfavorable to the latter. He says: “They have based their calculations on the cost of steam, on large compound engines of 1000 or more H. P. and 120 pounds pressure of steam in their boilers, and by careful 10-hour trials succeeded in figuring down steam to a cost of about  $\$20$  per H. P., ignoring the well-known fact that its average cost in practical use, except near the coal mines, is from  $\$40$  to  $\$50$ . In many instances dams, canals, and modern turbines can be all completed for a cost of  $\$100$  per H. P.: and the interest on that, and the cost of attendance and oil, will bring water-power up to but about  $\$10$  or  $\$12$  per annum; and with a man competent to attend the dynamo in attendance, it can probably be safely estimated at not over  $\$15$  per H. P.”

TURBINE WHEELS.

**Proportions of Turbines.**—Prof. De Volson Wood discusses at length the theory of turbines in his paper on Hydraulic Reaction Motors, *Trans. A. S. M. E.* xiv. 266. His principal deductions which have an immediate bearing upon practice are condensed in the following:

*Notation.*

- $Q$  = volume of water passing through the wheel per second,
- $h_1$  = head in the supply chamber above the entrance to the buckets,
- $h_2$  = head in the tail-race above the exit from the buckets,
- $z_1$  = fall in passing through the buckets.
- $H = h_1 + z_1 - h_2$ , the effective head,
- $\mu_1$  = coefficient of resistance along the guides,
- $\mu_2$  = coefficient of resistance along the buckets,
- $r_1$  = radius of the initial rim,
- $r_2$  = radius of the terminal rim,
- $V$  = velocity of the water issuing from supply chamber,
- $v_1$  = initial velocity of the water in the bucket in reference to the bucket,
- $v_2$  = terminal velocity in the bucket,
- $\omega$  = angular velocity of the wheel,
- $\alpha$  = terminal angle between the guide and initial rim =  $CAB$ , Fig. 132,
- $\gamma_1$  = angle between the initial element of bucket and initial rim =  $EAD$ ,
- $\gamma_2 = GFI$ , the angle between the terminal rim and terminal element of the bucket,
- $\alpha = eb$ , Fig. 133 = the arc subtending one gate opening,

$\alpha_1$  = the arc subtending one bucket at entrance. (In practice  $\alpha_1$  is larger than  $\alpha$ .)

$\alpha_2 = gh$ , the arc subtending one bucket at exit,

$K = bf$ , normal section of passage, it being assumed that the passages and buckets are very narrow,

$k_1 = bd$ , initial normal section of bucket,

$k_2 = gi$ , terminal normal section,

$\omega r_1$  = velocity of initial rim,

$\omega r_2$  = velocity of terminal rim,

$\theta = HFI$ , angle between the terminal rim and actual direction of the water at exit,

$Y$  = depth of  $K$ ,  $y$ , of  $\alpha_1$ , and  $y_2$  of  $K_2$ , then

$K = Y\alpha \sin \alpha$ ;  $K_1 = y_1 \alpha_1 \sin \gamma_1$ ;  $K_2 = y_2 \alpha_2 \sin \gamma_2$ .

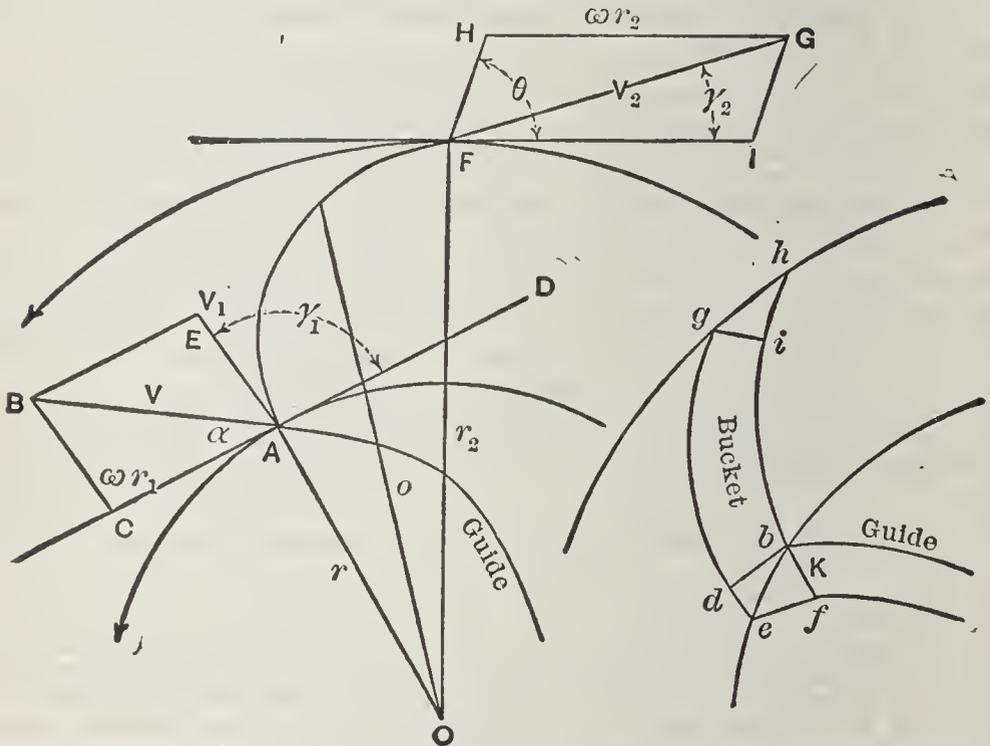

FIG. 132.

FIG. 133.

Three simple systems are recognized,  $r_1 < r_2$ , called outward flow;  $r_1 > r_2$ , called inward flow;  $r_1 = r_2$ , called parallel flow. The first and second may be combined with the third, making a mixed system.

*Value of  $\gamma_2$  (the quitting angle).*—The efficiency is increased as  $\gamma_2$  decreases, and is greatest for  $\gamma_2 = 0$ . Hence, theoretically, the terminal element of the bucket should be tangent to the quitting rim for best efficiency. This, however, for the discharge of a finite quantity of water, would require an infinite depth of bucket. In practice, therefore, this angle must have a finite value. The larger the diameter of the terminal rim the smaller may be this angle for a given depth of wheel and given quantity of water discharged. In practice  $\gamma_2$  is from  $10^\circ$  to  $20^\circ$ .

In a wheel in which all the elements except  $\gamma_2$  are fixed, the velocity of the wheel for best effect must increase as the quitting angle of the bucket decreases.

*Values of  $\alpha + \gamma_1$*  must be less than  $180^\circ$ , but the best relation cannot be determined by analysis. However, since the water should be deflected from its course as much as possible from its entering to its leaving the wheel, the angle  $\alpha$  for this reason should be as small as practicable.

In practice,  $\alpha$  cannot be zero, and is made from  $20^\circ$  to  $30^\circ$ .

The value  $r_1 = 1.4r_2$  makes the width of the crown for internal flow about the same as for  $r_1 = r_2 \sqrt{1/2}$  for outward flow, being approximately 0.3 of the external radius.

*Values of  $\mu_1$  and  $\mu_2$ .*—The frictional resistances depend upon the construction of the wheel as to smoothness of the surfaces, sharpness of the angles,

regularity of the curved parts, and also upon the speed it is run. These values cannot be definitely assigned beforehand, but Weisbach gives for good conditions  $\mu_1 = \mu_2 = 0.05$  to  $0.10$ .

They are not necessarily equal, and  $\mu_1$  may be from  $0.05$  to  $0.075$ , and  $\mu_2$  from  $0.06$  to  $0.10$  or even larger.

Values of  $\gamma_1$  must be less than  $180^\circ - \alpha$ .

To be on the safe side,  $\gamma_1$  may be  $20$  or  $30$  degrees less than  $180^\circ - 2\alpha$ , giving

$$\gamma_1 = 180^\circ - 2\alpha - 25 \text{ (say)} = 155 - 2\alpha.$$

Then if  $\alpha = 30^\circ$ ,  $\gamma_1 = 95^\circ$ . Some designers make  $\gamma_1$   $90^\circ$ ; others more, and still others less, than that amount. Weisbach suggests that it be less, so that the bucket will be shorter and friction less. This reasoning appears to be correct for the inflow wheel, but not for the outflow wheel. In the Tremont turbines, described in the Lowell Hydraulic Experiments, this angle is  $90^\circ$ , the angle  $\alpha$   $20^\circ$ , and  $\gamma_2$   $10^\circ$ , which proportions insured a positive pressure in the wheel. Fourneyron made  $\gamma_1 = 90^\circ$ , and  $\alpha$  from  $30^\circ$  to  $33^\circ$ , which values made the initial pressure in the wheel near zero.

*Form of Bucket.*—The form of the bucket cannot be determined analytically. From the initial and terminal directions and the volume of the water flowing through the wheel, the area of the normal sections may be found.

The normal section of the buckets will be:

$$K = \frac{Q}{V}; \quad k_1 = \frac{Q}{v_1}; \quad k_2 = \frac{Q}{v_2}.$$

The depths of those sections will be:

$$Y = \frac{K}{a \sin \alpha}; \quad y_1 = \frac{k_1}{a_1 \sin \gamma_1}; \quad y_2 = \frac{k_2}{a_2 \sin \gamma_2}.$$

The changes of curvature and section must be gradual, and the general form regular, so that eddies and whirls shall not be formed. For the same reason the wheel must be run with the correct velocity to secure the best effect. In practice the buckets are made of two or three arcs of circles, mutually tangential.

*The Value of  $\omega$ .*—So far as analysis indicates, the wheel may run at any speed; but in order that the stream shall flow smoothly from the supply chamber into the bucket, the velocity  $V$  should be properly regulated.

If  $\mu_1 = \mu_2 = 0.10$ ,  $r_2 \div r_1 = 1.40$ ,  $\alpha = 25^\circ$ ,  $\gamma_1 = 90^\circ$ ,  $\gamma_2 = 12^\circ$ , the velocity of the initial rim for outward flow will be for maximum efficiency  $0.614$  of the velocity due to the head, or  $\omega r_1 = 0.614 \sqrt{2gH}$ .

The velocity due to the head would be  $\sqrt{2gH} = 1.414 \sqrt{gH}$ .

For an inflow wheel for the case in which  $r_1^2 = 2r_2^2$ , and the other dimensions as given above,  $\omega r_1 = 0.682 \sqrt{2gH}$ .

The highest efficiency of the Tremont turbine, found experimentally, was  $0.79375$ , and the corresponding velocity,  $0.62645$  of that due to the head, and for all velocities above and below this value the efficiency was less.

In the Tremont wheel  $\alpha = 20^\circ$  instead of  $25^\circ$ , and  $\gamma_2 = 10^\circ$  instead of  $12^\circ$ . These would make the theoretical efficiency and velocity of the wheel somewhat greater. Experiment showed that the velocity might be considerably larger or smaller than this amount without much diminution of the efficiency.

It was found that if the velocity of the initial (or interior) rim was not less than  $44\%$  nor more than  $75\%$  of that due to the fall, the efficiency was  $75\%$  or more. This wheel was allowed to run freely without any brake except its own friction, and the velocity of the initial rim was observed to be  $1.335 \sqrt{2gH}$ , half of which is  $0.6675 \sqrt{2gH}$ , which is not far from the velocity giving maximum effect; that is to say, when the gate is fully raised the coefficient of effect is a maximum when the wheel is moving with about half its maximum velocity.

*Number of Buckets.*—Successful wheels have been made in which the distance between the buckets was as small as  $0.75$  of an inch, and others as much as  $2.75$  inches. Turbines at the Centennial Exposition had buckets from  $4\frac{1}{2}$  inches to  $9$  inches from centre to centre. If too large they will not work properly. Neither should they be too deep. Horizontal partitions are sometimes introduced. These secure more efficient working in case the gates are only partly opened. The form and number of buckets for commercial purposes are chiefly the result of experience.

**Ratio of Radii.**—Theory does not limit the dimensions of the wheel. In practice,

for outward flow,  $r_2 \div r_1$  is from 1.25 to 1.50;  
for inward flow,  $r_2 \div r_1$  is from 0.66 to 0.80.

It appears that the inflow-wheel has a higher efficiency than the outward-flow wheel. The inflow-wheel also runs somewhat slower for best effect. The centrifugal force in the outward-flow wheel tends to force the water outward faster than it would otherwise flow; while in the inward-flow wheel it has the contrary effect, acting as it does in opposition to the velocity in the buckets.

It also appears that the efficiency of the outward-flow wheel increases slightly as the width of the crown is less and the velocity for maximum efficiency is slower; while for the inflow-wheel the efficiency slightly increases for increased width of crown, and the velocity of the outer rim at the same time also increases.

**Efficiency.**—The exact value of the efficiency for a particular wheel must be found by experiment.

It seems hardly possible for the effective efficiency to equal, much less exceed, 80%, and all claims of 90 or more per cent for these motors should be discarded as improbable. A turbine yielding from 75% to 80% is extremely good. Experiments with higher efficiencies have been reported.

The celebrated Tremont turbine gave 79¼% without the "diffuser," which might have added some 2%. A Jonval turbine (parallel flow) was reported as yielding 0.75 to 0.90, but Morin suggested corrections reducing it to 0.63 to 0.71. Weisbach gives the results of many experiments, in which the efficiency ranged from 50% to 84%. Numerous experiments give  $E = 0.60$  to 0.65. The efficiency, considering only the energy imparted to the wheel, will exceed by several per cent the efficiency of the wheel, for the latter will include the friction of the support and leakage at the joint between the sluice and wheel, which are not included in the former; also as a plant the resistances and losses in the supply-chamber are to be still further deducted.

**The Crowns.**—The crowns may be plane annular disks, or conical, or curved. If the partitions forming the buckets be so thin that they may be discarded, the law of radial flow will be determined by the form of the crowns. If the crowns be plane, the radial flow (or radial component) will diminish, for the outward flow-wheel, as the distance from the axis increases—the buckets being full—for the angular space will be greater.

Prof. Wood deduces from the formulæ in his paper the tables on page 595. It appears from these tables: 1. That the terminal angle,  $\alpha$ , has frequently been made too large in practice for the best efficiency.

2. That the terminal angle,  $\alpha$ , of the guide should be for the inflow less than  $10^\circ$  for the wheels here considered, but when the initial angle of the bucket is  $90^\circ$ , and the terminal angle of the guide is  $5^\circ 28'$ , the gain of efficiency is not 2% greater than when the latter is  $25^\circ$ .

3. That the initial angle of the bucket should exceed  $90^\circ$  for best effect for outflow-wheels.

4. That with the initial angle between  $60^\circ$  and  $120^\circ$  for best effect on inflow wheels the efficiency varies scarcely 1%.

5. In the outflow-wheel, column (9) shows that for the outflow for best effect the direction of the quitting water in reference to the earth should be nearly radial (from  $76^\circ$  to  $97^\circ$ ), but for the inflow wheel the water is thrown forward in quitting. This shows that the velocity of the rim should somewhat exceed the relative final velocity backward in the bucket, as shown in columns (4) and (5).

6. In these tables the velocities given are in terms of  $\sqrt{2gh}$ , and the coefficients of this expression will be the part of the head which would produce that velocity if the water issued freely. There is only one case, column (5), where the coefficient exceeds unity, and the excess is so small it may be discarded; and it may be said that in a properly proportioned turbine with the conditions here given none of the velocities will equal that due to the head in the supply-chamber when running at best effect.

7. The inflow turbine presents the best conditions for construction for producing a given effect, the only apparent disadvantage being an increased first cost due to an increased depth, or an increased diameter for producing a given amount of work. The larger efficiency should, however, more than neutralize the increased first cost.

**Outward-flow Turbine.**

$r_1 = r_2 \sqrt{\frac{1}{2}}$        $\mu_1 = \mu_2 = 0.10.$        $\gamma_2 = 12^\circ.$       Parallel Crowns.       $k_1 v_1 = k_2 v_2 = KV = Q = 1.$

**Tests of Turbines.**—Emerson says that in testing turbines it is a rare thing to find two of the same size which can be made to do their best at the same speed. The best speed of one of the leading wheels is invariably wide from the tabled rate. It was found that a 54-in. Leffel wheel under 12 ft. head gave much better results at 78 revolutions per minute than at 90.

Overshot wheels have been known to give 75% efficiency, but the average performance is not over 60%.

A fair average for a good turbine wheel may be taken at 75%. In tests of 18 wheels made at the Philadelphia Water-works in 1859 and 1860, one wheel gave less than 50% efficiency, two between 50% and 60%, six between 60% and 70%, seven between 71% and 77%, two 82%, and one 87.77%. (Emerson.)

**Tests of Turbine Wheels at the Centennial Exhibition, 1876.** (From a paper by R. H. Thurston on The Systematic Testing of Turbine Wheels in the United States, Trans. A. S. M. E., viii. 359.)—In 1876 the judges at the International Exhibition conducted a series of trials of turbines. Many of the wheels offered for tests were found to be more or less defective in fitting and workmanship. The following is a statement of the results of all turbines entered which gave an efficiency of over 75%. Seven other wheels were tested, giving results between 65% and 75%.

Maker's Name, or Name the Wheel is Known By.	Per Cent at Full Gate or Discharge.	Per Cent at about 9/10 of Full Discharge.	Per Cent at about 7/8 of Full Discharge.	Per Cent at about 3/4 of Full Discharge.	Per Cent at about 5/8 of Full Discharge.	Per Cent at about 1/2 of Full Discharge.	Per Cent at about 4/10 of Full Discharge.

The limits of error of the tests, says Prof. Thurston, were very uncertain; they are undoubtedly considerable as compared with the later work done in the permanent flume at Holyoke—possibly as much as 4% or 5%.

Experiments with "draught-tubes," or "suction-tubes," which were actually "diffusers" in their effect, so far as Prof. Thurston has analyzed them, indicate the loss by friction which should be anticipated in such cases, this loss decreasing as the tube increased in size, and increasing as its diameter approached that of the wheel—the minimum diameter tried. It was sometimes found very difficult to free the tube from air completely, and next to impossible, during the interval, to control the speed with the brake. Several trials were often necessary before the power due to the full head could be obtained. The loss of power by gearing and by belting was variable with the proportions and arrangement of the gears and pulleys, length of belt, etc., but averaged not far from 30% for a single pair of bevel-gears, uncut and dry, but smooth for such gearing, and but 10% for the same gears, well lubricated, after they had been a short time in operation. The amount of power transmitted was, however, small, and these figures are probably much higher than those representing ordinary practice. Introducing a second pair—spur-gears—the best figures were but little changed, although the difference between the case in which the larger gear was the driver, and the case in which the small wheel was the driver, was perceptible, and was in favor of the former arrangement. A single straight belt gave a loss of but 2% or 3%, a crossed belt 6% to 8%, when transmitting 14

horse-power with maximum tightness and transmitting power. A "quarter turn" wasted about 10% as a maximum, and a "quarter twist" about 5%.

**Dimensions of Turbines.**—For dimensions, power, etc., of standard makes of turbines consult the catalogues of different manufacturers. The wheels of different makers vary greatly in their proportions for any given capacity.

**The Pelton Water-wheel.**—Mr. Ross E. Browne (*Eng'g News*, Feb. 20, 1892) thus outlines the principles upon which this water-wheel is constructed:

The function of a water-wheel, operated by a jet of water escaping from a nozzle, is to convert the energy of the jet, due to its velocity, into useful work. In order to utilize this energy fully the wheel-bucket, after catching the jet, must bring it to rest before discharging it, without inducing turbulence or agitation of the particles.

This cannot be fully effected, and unavoidable difficulties necessitate the loss of a portion of the energy. The principal losses occur as follows: First, in sharp or angular diversion of the jet in entering, or in its course through the bucket, causing impact, or the conversion of a portion of the energy into heat instead of useful work. Second, in the so-called frictional resistance offered to the motion of the water by the wetted surfaces of the buckets, causing also the conversion of a portion of the energy into heat instead of useful work. Third, in the velocity of the water, as it leaves the bucket, representing energy which has not been converted into work.

Hence, in seeking a high efficiency: 1. The bucket-surface at the entrance should be approximately parallel to the relative course of the jet, and the bucket should be curved in such a manner as to avoid sharp angular deflection of the stream. If, for example, a jet strikes a surface at an angle and is sharply deflected, a portion of the water is backed, the smoothness of the stream is disturbed, and there results considerable loss by impact and otherwise. The entrance and deflection in the Pelton bucket are such as to avoid these losses in the main. (See Fig. 136.)

2. The number of buckets should be small, and the path of the jet in the bucket short; in other words, the total wetted surface should be small, as the loss by friction will be proportional to this.

3. The discharge end of the bucket should be as nearly tangential to the wheel periphery as compatible with the clearance of the bucket which follows; and great differences of velocity in the parts of the escaping water should be avoided. In order to bring the water to rest at the discharge end of the bucket, it is shown, mathematically, that the velocity of the bucket should be one half the velocity of the jet.

FIG. 134.

FIG. 135.

A bucket, such as shown in Fig. 135, will cause the heaping of more or less dead or turbulent water at the point indicated by dark shading. This dead water is subsequently thrown from the wheel with considerable velocity, and represents a large loss of energy. The introduction of the wedge in the Pelton bucket (see Fig. 134) is an efficient means of avoiding this loss.

A wheel of the form of the Pelton conforms closely in construction to each of these requirements.

In a test made by the proprietors of the Idaho mine, near Grass Valley, Cal., the dimensions and results were as follows: Main supply-pipe, 22 in. diameter, 6900 ft.

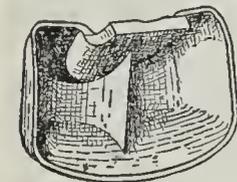

FIG. 136.

long, with a head of  $386\frac{1}{2}$  feet above centre of nozzle. The loss by friction in the pipe was 1.8 ft., reducing the effective head to 384.7 ft. The Pelton wheel used in the test was 6 ft. in diameter and the nozzle was 1.89 in. diameter. The work done was measured by a Prony brake, and the mean of 13 tests showed a useful effect of 87.3%.

The Pelton wheel is also used as a motor for small powers. A test by M. E. Cooley of a 12-inch wheel, with a  $\frac{3}{8}$ -inch nozzle, under 100 lbs. pressure, gave 1.9 horse-power. The theoretical discharge was .0935 cubic feet per second, and the theoretical horse-power 2.45; the efficiency being 80 per cent. Two other styles of water-motor tested at the same time each gave efficiencies of 55 per cent.

**Pelton Water-wheel Tables. (Abridged.)**

The smaller figures under those denoting the various heads give the spouting velocity of the water in feet per minute. The cubic-foot measurement is also based on the flow per minute.

**THE POWER OF OCEAN WAVES.**

Albert W. Stahl, U. S. N. (Trans. A. S. M. E., xiii. 438), gives the following formulæ and table, based upon a theoretical discussion of wave motion:

The total energy of one whole wave-length of a wave  $H$  feet high,  $L$  feet long, and one foot in breadth, the length being the distance between successive crests, and the height the vertical distance between the crest and the trough, is  $E = 8LH^2 \left( 1 - 4.935 \frac{H^2}{L^2} \right)$  foot-pounds.

The time required for each wave to travel through a distance equal to its own length is  $P = \sqrt{\frac{L}{5.123}}$  seconds, and the number of waves passing any

given point in one minute is  $N = \frac{60}{P} = 60 \sqrt{\frac{5.123}{L}}$ . Hence the total energy of an indefinite series of such waves, expressed in horse-power per foot of breadth, is

$$\frac{E \times N}{33000} = .0329 H^2 L \left( 1 - 4.935 \frac{H^2}{L^2} \right).$$

By substituting various values for  $H + L$ , within the limits of such values actually occurring in nature, we obtain the following table of

**TOTAL ENERGY OF DEEP-SEA WAVES IN TERMS OF HORSE-POWER PER FOOT OF BREADTH.**

Ratio of Length of Waves to Height of Waves.	Length of Waves in Feet.							
	25	50	75	100	150	200	300	400
50	.04	.23	.64	1.31	3.62	7.43	20.46	42.01
40	.06	.36	1.00	2.05	5.65	11.59	31.95	65.58
30	.12	.64	1.77	3.64	10.02	20.57	56.70	116.38
20	.25	1.44	3.96	8.13	21.79	45.98	126.70	260.08
15	.42	2.83	6.97	14.31	39.43	80.94	223.06	457.89
10	.98	5.53	15.24	31.29	86.22	177.00	487.75	1001.25
5	3.30	18.68	51.48	105.68	291.20	597.78	1647.31	3381.60

The figures are correct for trochoidal deep-sea waves only, but they give a close approximation for any nearly regular series of waves in deep water and a fair approximation for waves in shallow water.

The question of the practical utilization of the energy which exists in ocean waves divides itself into several parts:

1. The various motions of the water which may be utilized for power purposes.

2. The wave motor proper. That is, the portion of the apparatus in direct contact with the water, and receiving and transmitting the energy thereof; together with the mechanism for transmitting this energy to the machinery for utilizing the same.

3. Regulating devices, for obtaining a uniform motion from the irregular and more or less spasmodic action of the waves, as well as for adjusting the apparatus to the state of the tide and condition of the sea.

4. Storage arrangements for insuring a continuous and uniform output of power during a calm, or when the waves are comparatively small.

The motions that may be utilized for power purposes are the following: 1. Vertical rise and fall of particles at and near the surface. 2. Horizontal to-and-fro motion of particles at and near the surface. 3. Varying slope of surface of wave. 4. Impetus of waves rolling up the beach in the form of breakers. 5. Motion of distorted verticals. All of these motions, except the last one mentioned, have at various times been proposed to be utilized for power purposes; and the last is proposed to be used in apparatus described by Mr. Stahl.

The motion of distorted verticals is thus defined: A set of particles, originally in the same vertical straight line when the water is at rest, does not remain in a vertical line during the passage of the wave; so that the line connecting a set of such particles, while vertical and straight in still water, becomes distorted, as well as displaced, during the passage of the wave, its upper portion moving farther and more rapidly than its lower portion.

Mr. Stahl's paper contains illustrations of several wave-motors designed upon various principles. His conclusions as to their practicability is as follows: "Possibly none of the methods described in this paper may ever prove commercially successful; indeed the problem may not be susceptible of a financially successful solution. My own investigations, however, so far as I have yet been able to carry them, incline me to the belief that wave-power can and will be utilized on a paying basis."

**Continuous Utilization of Tidal Power.** (P. Decœur, Proc. Inst. C. E. 1890.)—In connection with the training-walls to be constructed in

the estuary of the Seine, it is proposed to construct large basins, by means of which the power available from the rise and fall of the tide could be utilized. The method proposed is to have two basins separated by a bank rising above high water, within which turbines would be placed. The upper basin would be in communication with the sea during the higher one third of the tidal range, rising, and the lower basin during the lower one third of the tidal range, falling. If  $H$  be the range in feet, the level in the upper basin would never fall below  $\frac{2}{3}H$  measured from low water, and the level in the lower basin would never rise above  $\frac{1}{3}H$ . The available head varies between  $0.53H$  and  $0.80H$ , the mean value being  $\frac{2}{3}H$ . If  $S$  square feet be the area of the lower basin, and the above conditions are fulfilled, a quantity  $\frac{1}{3}SH$  cu. ft. of water is delivered through the turbines in the space of  $9\frac{1}{4}$  hours. The mean flow is, therefore,  $SH \div 99,900$  cu. ft. per sec., and, the mean fall being  $\frac{2}{3}H$ , the available gross horse-power is about  $\frac{1}{30}S'H^2$ , where  $S'$  is measured in acres. This might be increased by about one third if a variation of level in the basins amounting to  $\frac{1}{2}H$  were permitted. But to reach this end the number of turbines would have to be doubled, the mean head being reduced to  $\frac{1}{2}H$ , and it would be more difficult to transmit a constant power from the turbines. The turbine proposed is of an improved model designed to utilize a large flow with a moderate diameter. One has been designed to produce 300 horse-power, with a minimum head of 5 ft. 3 in. at a speed of 15 revolutions per minute, the vanes having 13 ft. internal diameter. The speed would be maintained constant by regulating sluices.

### PUMPS AND PUMPING ENGINES.

**Theoretical Capacity of a Pump.**—Let  $Q'$  = cu. ft. per min.;  $G'$  = Amer. gals. per min. =  $7.4805Q'$ ;  $d$  = diam. of pump in inches;  $l$  = stroke in inches;  $N$  = number of single strokes per min.

$$\text{Capacity in cu. ft. per min.} = Q' = \frac{\pi}{4} \cdot \frac{d^2}{144} \cdot \frac{lN}{12} = .0004545Nd^2l;$$

$$\text{Capacity in gals. per min. } G' = \frac{\pi}{4} \cdot \frac{Nd^2l}{231} \dots\dots\dots = .0034Nd^2l;$$

$$\text{Capacity in gals. per hour} \dots\dots\dots = .204Nd^2l.$$

$$\text{Diameter required for a } \left. \begin{array}{l} \\ \text{given capacity per min.} \end{array} \right\} d = 46.9 \sqrt{\frac{Q'}{Nl}} = 17.15 \sqrt{\frac{G'}{Nl}}.$$

$$\text{If } v = \text{piston speed in feet per min., } d = 13.54 \sqrt{\frac{Q'}{v}} = 4.95 \sqrt{\frac{G'}{v}}.$$

If the piston speed is 100 feet per min.:

$$Nl = 1200, \text{ and } d = 1.354 \sqrt{Q'} = .495 \sqrt{G'}; \quad G' = 4.08d^2 \text{ per min.}$$

The actual capacity will be from 60% to 95% of the theoretical, according to the tightness of the piston, valves, suction-pipe, etc.

**Theoretical Horse-power required to raise Water to a given Height.**—Horse-power =

$$\frac{\text{Volume in cu. ft. per min.} \times \text{pressure per sq. ft.}}{33,000} = \frac{\text{Weight} \times \text{height of lift}}{33,000}.$$

$Q'$  = cu. ft. per min.;  $G'$  = gals. per min.;  $W$  = wt. in lbs.;  $P$  = pressure in lbs. per sq. ft.;  $p$  = pressure in lbs. per sq. in.;  $H$  = height of lift in ft.;  $W = 62.36Q'$ ,  $P = 144p$ ,  $H = 2.309p$ ,  $G' = 7.4805Q'$ .

$$\text{HP} = \frac{Q'P}{33,000} = \frac{Q'H \times 144 \times .433}{33,000} = \frac{Q'H}{529.2} = \frac{G'H}{3958.7};$$

$$\text{HP} = \frac{WH}{33,000} = \frac{Q' \times 62.36 \times 2.309p}{33,000} = \frac{Q'p}{229.2} = \frac{G'p}{1714.5}.$$

For the actual horse-power required an allowance must be made for the friction, slips, etc., of engine, pump, valves, and passages.

**Depth of Suction.**—Theoretically a perfect pump will draw water from a height of nearly 34 feet, or the height corresponding to a perfect vacuum (14.7 lbs.  $\times$  2.309 = 33.95 feet); but since a perfect vacuum cannot be obtained, on account of valve-leakage, air contained in the water, and the vapor of the water itself, the actual height is generally less than 30 feet. When the water is warm the height to which it can be lifted by suction decreases, on account of the increased pressure of the vapor. In pumping hot water, therefore, the water must flow into the pump by gravity. The following table shows the theoretical maximum depth of suction for different temperatures, leakage not considered:

Temp. F.	Absolute Pressure of Vapor, lbs. per sq. in.	Vacuum in Inches of Mercury.	Max. Depth of Suction, feet.	Temp. F.	Absolute Pressure of Vapor, lbs. per sq. in.	Vacuum in Inches of Mercury.	Max. Depth of Suction, feet.
102.1	1	27.88	31.6	182.9	8	13.63	15.4

153.1	4	21.78	24.7	197.8	11	7.52	8.5
162.3	5	19.74	22.3	202.0	12	5.49	6.2
170.1	6	17.70	20.0	205.9	13	3.45	3.9
176.9	7	15.67	17.7	209.6	14	1.41	1.6

### Amount of Water raised by a Single-acting Lift-pump.

—It is common to estimate that the quantity of water raised by a single-acting bucket-valve pump per minute is equal to the number of strokes in one direction per minute, multiplied by the volume traversed by the piston in a single stroke, on the theory that the water rises in the pump only when the piston or bucket ascends; but the fact is that the column of water does not cease flowing when the bucket descends, but flows on continuously through the valve in the bucket, so that the discharge of the pump, if it is operated at a high speed, may amount to nearly double that calculated from the displacement multiplied by the number of single strokes in one direction.

### Proportioning the Steam-cylinder of a Direct-acting Pump.—Let

$A$  = area of steam-cylinder;  $a$  = area of pump-cylinder;  
 $D$  = diameter of steam-cylinder;  $d$  = diameter of pump-cylinder;  
 $P$  = steam-pressure, lbs. per sq. in.;  $p$  = resistance per sq. in. on pumps;  
 $H$  = head = 2.309 $p$ ;  $p = .433H$ ;

$E$  = efficiency of the pump =  $\frac{\text{work done in pump-cylinder}}{\text{work done by the steam-cylinder}}$ .

$$A = \frac{ap}{EP}; \quad a = \frac{EAP}{p}; \quad D = d\sqrt{\frac{p}{EP}}; \quad d = D\sqrt{\frac{EP}{p}}; \quad P = \frac{ap}{EA}; \quad p = \frac{EAP}{a}.$$

$$\frac{A}{a} = \frac{p}{EP} = \frac{.433H}{EP}; \quad H = 2.309EP \frac{A}{a}; \quad \text{If } E = 75\%, \quad H = 1.732P \frac{A}{a}.$$

$E$  is commonly taken at 0.7 to 0.8 for ordinary direct-acting pumps. For the highest class of pumping-engines it may amount to 0.9. The steam-pressure  $P$  is the mean effective pressure, according to the indicator-diagram; the water-pressure  $p$  is the mean total pressure acting on the pump plunger or piston, including the suction, as could be shown by an indicator-diagram of the water-cylinder. The pressure on the pump-piston is frequently much greater than that due to the height of the lift, on account of the friction of the valves and passages, which increases rapidly with velocity of flow.

### Speed of Water through Pipes and Pump-passages.—

The speed of the water is commonly from 100 to 200 feet per minute. If 200 feet per minute is exceeded, the loss from friction may be considerable.

The diameter of pipe required is  $4.95\sqrt{\frac{\text{gallons per minute}}{\text{velocity in feet per minute}}}$ .

For a velocity of 200 feet per minute, diameter =  $.35 \times \sqrt{\text{gallons per min.}}$

**Sizes of Direct-acting Pumps.**—The tables on this and the next page are selected from catalogues of manufacturers, as representing the two common types of direct-acting pump, viz., the single-cylinder and the duplex. Both types are now made by most of the leading manufacturers.

**The Deane Single Boiler-feed or Pressure Pump.**—Suitable for pumping clear liquids at a pressure not exceeding 150 lbs.

**Efficiency of Small Direct-acting Pumps.**—Chas. E. Emery, in Reports of Judges of Philadelphia Exhibition, 1876, Group xx., says: "Experiments made with steam-pumps at the American Institute Exhibition of 1867 showed that average-sized steam-pumps do not, on the average, utilize more than 50 per cent of the indicated power in the steam-cylinders, the remainder being absorbed in the friction of the engine, but more particularly in the passage of the water through the pump. It may be safely stated that ordinary steam-pumps rarely require less than 120 pounds of steam per hour for each horse-power utilized in raising water, equivalent to a duty of only 15,000,000 foot-pounds per 100 pounds of coal. With larger steam-pumps, particularly when they are proportioned for the work to be done, the duty will be materially increased."

### The Worthington Duplex Pump.

STANDARD SIZES FOR ORDINARY SERVICE.

Diameter of Steam-cylinders.	Diameter of Water-plungers.	Length of Stroke.	Displacement in Gallons per Stroke of One Plunger.	Proper Strokes per Minute of One Plunger, varying with kind of work and pressure.	Gallons delivered per Minute by both Plungers at stated Number of Strokes.	Diameter of Plunger required in any single-cylinder pump to do the same work at same speed.	Sizes of Pipes for Short Lengths. To be increased as length increases.

**Speed of Piston.**—A piston speed of 100 feet per minute is commonly assumed as correct in practice, but for short-stroke pumps this gives too high a speed of rotation, requiring too frequent a reversal of the valves. For long-stroke pumps, 2 feet and upward, this speed may be considerably exceeded, if valves and passages are of ample area.

**Number of Strokes required to Attain a Piston Speed from 50 to 125 Feet per Minute for Pumps having Strokes from 3 to 18 Inches in Length.**

Speed of Piston, in feet per min.	Length of Stroke in Inches.

**Piston Speed of Pumping-engines.** (John Birkinbine, Trans. A. I. M. E., v. 459.)—In dealing with such a ponderous and unyielding substance as water there are many difficulties to overcome in making a pump work with a high piston speed. The attainment of moderately high speed is, however, easily accomplished. Well-proportioned pumping-engines of large capacity, provided with ample water-ways and properly constructed valves, are operated successfully against heavy pressures at a speed of 250 ft. per minute, without "thug," concussion, or injury to the apparatus, and there is no doubt that the speed can be still further increased.

**Speed of Water through Valves.**—If areas through valves and water passages are sufficient to give a velocity of 250 ft. per min. or less, they are ample. The water should be carefully guided and not too abruptly deflected. (F. W. Dean, *Eng. News*, Aug. 10, 1893.)

**Boiler-feed Pumps.**—Practice has shown that 100 ft. of piston speed per minute is the limit, if excessive wear and tear is to be avoided.

The velocity of water through the suction-pipe must not exceed 200 ft. per minute, else the resistance of the suction is too great.

The approximate size of suction-pipe, where the length does not exceed 25 ft. and there are not more than two elbows, may be found as follows:

$\frac{7}{10}$  of the diameter of the cylinder multiplied by  $\frac{1}{100}$  of the piston speed in feet. For duplex pumps of small size, a pipe one size larger is usually employed. The velocity of flow in the discharge-pipe should not exceed 500 ft. per minute. The volume of discharge and length of pipe vary so greatly in different installations that where the water is to be forced more than 50 ft. the size of discharge-pipe should be calculated for the particular conditions, allowing no greater velocity than 500 ft. per minute. The size of discharge-pipe is calculated in single-cylinder pumps from 250 to 400 ft. per minute. Greater velocity is permitted in the larger pipes.

In determining the proper size of pump for a steam-boiler, allowances must be made for a supply of water sufficient to cover all the demands of engines, steam-heating, etc., up to the capacity of generator, and should not be calculated simply according to the requirements of the engine. In practice engines use all the way from 12 up to 50, or more, pounds of steam per H.P. per hour when being worked up to capacity. When an engine is overloaded or underloaded more water per H.P. will be required than when operating at its rated capacity. The average run of horizontal tubular

boilers will evaporate from 2 to 3 lbs. of water per sq. ft. of heating-surface per hour, but may be driven up to 6 lbs. if the grate-surface is too large or the draught too great for economical working.

**Pump-Valves.**—A. F. Nagle (*Trans. A. S. M. E.*, x, 521) gives a number of designs with dimensions of double-beat or Cornish valves used in large pumping-engines, with a discussion of the theory of their proportions. The following is a summary of the proportions of the valves described.

SUMMARY OF VALVE PROPORTIONS.

Location of Engine.	Diam. of Valve in inches.	Weight in Water per square inch of Inside Unbalanced Area, in lbs.	Ratio of Seat-area to Inside Unbalanced Area.	Pressure upon Seat per sq. in., in lbs.	Action.
Providence high-service engine .....	12	1 lb. reduced to .66 lb.	16%	377 lbs.	Good
Providence Cornish-engine.....	16	1.28	12	680	Good Some noise Some noise at high speed. Noisy
St. Louis Water Wks.	16	1.86	67	250

wood seats.....	15	1.16	94	132	"
Chicago Water Wks.	8	.96	75	151	"

Mr. Nagle says: There is one feature in which the Cornish valves are necessarily defective, namely, the lift must always be quite large, unless great power is sacrificed to reduce it. It is undeniable that a small lift is preferable to a great one, and hence it naturally leads to the substitution of numerous small valves for one or several large ones. To what extreme reduction of size this view might safely lead must be left to the judgment of the engineer for the particular case in hand, but certainly, theoretically, we must adopt small valves. Mr. Corliss at one time carried the theory so far as to make them only  $1\frac{3}{8}$  inches in diameter, but from 3 to 4 inches is the more common practice now. A small valve presents proportionately a larger surface of discharge with the same lift than a larger valve, so that whatever the total area of valve-seat opening, its full contents can be discharged with less lift through numerous small valves than with one large one.

Henry R. Worthington was the first to use numerous small rubber valves in preference to the larger metal valves. These valves work well under all the conditions of a city pumping-engine. A volute spring is generally used to limit the rise of the valve.

In the Leavitt high-duty sewerage-engine at Boston (*Am. Machinist*, May 31, 1884), the valves are of rubber,  $\frac{3}{4}$ -inch thick, the opening in valve-seat being  $13\frac{1}{2} \times 4\frac{1}{2}$  inches. The valves have iron face and back-plates, and form their own hinges.

### CENTRIFUGAL PUMPS.

**Relation of Height of Lift to Velocity.**—The height of lift depends only on the tangential velocity of the circumference, every tangential velocity giving a constant height of lift—sometimes termed "head"—whether the pump is small or large. The quantity of water discharged is in proportion to the area of the discharging orifices at the circumference, or in proportion to the square of the diameter, when the breadth is kept the same. R. H. Buel (*App. Cyc. Mech.*, ii, 606) gives the following:

Let  $Q$  represent the quantity of water, in cubic feet, to be pumped per minute,  $h$  the height of suction in feet,  $h'$  the height of discharge in feet, and  $d$  the diameter of suction-pipe, equal to the diameter of discharge-pipe, in

feet; then, according to Fink,  $d = 0.36 \sqrt{\frac{Q}{\sqrt{2g(h+h')}}}$ ,  $g$  being the acceleration due to gravity.

If the suction takes place on one side of the wheel, the inside diameter of the wheel is equal to  $1.2d$ , and the outside to  $2.4d$ . If the suction takes place at both sides of the wheel, the inside diameter of the wheel is equal to  $0.85d$ , and the outside to  $1.7d$ . Then the suction-pipe will have two branches, the area of each equal to half the area of  $d$ . The suction-pipe should be as short as possible, to prevent air from entering the pump. The tangential velocity of the outer edge of wheel for the delivery  $Q$  is equal to  $1.25 \sqrt{2g(h+h')}$  feet per second.

The arms are six in number, constructed as follows: Divide the central angle of  $60^\circ$ , which incloses the outer edges of the two arms, into any number of equal parts by drawing the radii, and divide the breadth of the wheel in the same manner by drawing concentric circles. The intersections of the several radii with the corresponding circles give points of the arm.

In experiments with Appold's pump, a velocity of circumference of 500 ft. per min. raised the water 1 ft. high, and maintained it at that level without discharging any; and double the velocity raised the water to four times the height, as the centrifugal force was proportionate to the square of the velocity; consequently,

500	ft.	per min.	raised	the	water	1	ft.	without	discharge.
1000	"	"	"	"	"	4	"	"	"
2000	"	"	"	"	"	16	"	"	"
4000	"	"	"	"	"	64	"	"	"

The greatest height to which the water had been raised without discharge, in the experiments with the 1-ft. pump, was 67.7 ft., with a velocity of 4153 ft. per min., being rather less than the calculated height, owing probably to leakage with the greater pressure. A velocity of 1128 ft. per min. raised the water  $5\frac{1}{2}$  ft. without any discharge, and the maximum effect from the power employed in raising to the same height  $5\frac{1}{2}$  ft. was obtained at the velocity of 1678 ft. per min., giving a discharge of 1400 gals. per min. from the 1-ft. pump. The additional velocity required to effect a discharge of 1400 gals. per min., through a 1-ft. pump working at a dead level without any height of lift, is 550 ft. per min. Consequently, adding this number in each case to the velocity given above, at which no discharge takes place, the following velocities are obtained for the maximum effect to be produced in each case:

1050	ft.	per min.	velocity for	1	ft.	height of lift.
1550	"	"	"	4	"	"
2550	"	"	"	16	"	"
4550	"	"	"	64	"	"

Or, in general terms, the velocity in feet per minute for the circumference of the pump to be driven, to raise the water to a certain height, is equal to  $550 + 500 \sqrt{\text{height of lift in feet.}}$

**Lawrence Centrifugal Pumps, Class B—For Lifts from 15 to 35 ft.**

No. of Pump.	Suction-pipe, in.	Discharge-pipe, in.	Economical Capacity, gals. per min.	H.P. for each foot of lift.	Weight, lbs.	No. of Pump.	Suction-pipe, in.	Discharge-pipe, in.	Economical Capacity, gals. per min.	H.P. for each foot of lift.	Weight, lbs.
1	$1\frac{1}{2}$	1	25	.028	65	10	10	10	3000	1.60	3000

**Efficiencies of Centrifugal and Reciprocating Pumps.—**

W. O. Webber (Trans. A. S. M. E., vii. 598) gives diagrams showing the relative efficiencies of centrifugal and reciprocating pumps, from which the following figures are taken for the different lifts stated :

Lift, feet:

2	5	10	15	20	25	30	35	40	50	60	80	100	120	160	200	240	280
Efficiency reciprocating pump:																	
..	..	.30	.45	.55	.61	.66	.68	.71	.75	.77	.82	.85	.87	.90	.89	.88	.85
Efficiency centrifugal pump:																	
.50	.56	.64	.68	.69	.68	.66	.62	.58	.50	.40	...	...	...	...	...	...	...

The term efficiency here used indicates the value of W. H. P. ÷ I. H. P., or horse-power of the water raised divided by the indicated horse-power of the steam-engine, and does not therefore show the full efficiency of the pump, but that of the combined pump and engine. It is, however, a very simple way of showing the relative values of different kinds of pumping-engines having their motive power forming a part of the plant.

The highest value of this term, given by Mr. Webber, is .9164 for a lift of 170 ft., and 3615 gals. per min. This was obtained in a test of the Leavitt pumping-engine at Lawrence, Mass., July 24, 1879.

With reciprocating pumps, for higher lifts than 170 ft., the curve of efficiencies falls, and from 200 to 300 ft. lift the average value seems about .84. Below 170 ft. the curve also falls reversely and slowly, until at about 90 ft. its descent becomes more rapid, and at 35 ft. .727 appears the best recorded performance. There are not any very satisfactory records below this lift, but some figures are given for the yearly coal consumption and total number of gallons pumped by engines in Holland under a 16-ft. lift, from which an efficiency of .44 has been deduced.

With centrifugal pumps, the lift at which the maximum efficiency is obtained is approximately 17 ft. At lifts from 12 to 18 ft. some makers of large experience claim now to obtain from 65% to 70% of useful effect, but .613 appears to be the best done at a public test under 14.7 ft. head.

The drainage-pumps constructed some years ago for the Haarlem Lake were designed to lift 70 tons per min. 15 ft., and they weighed about 150 tons. Centrifugal pumps for the same work weigh only 5 tons. The weight of a centrifugal pump and engine to lift 10,000 gals. per min. 35 ft. high is 6 tons.

The pumps placed by Gwynne at the Ferrara Marshes, Northern Italy, in 1865, are, it is believed, capable of handling more water than other set of pumping-engines in existence. The work performed by these pumps is the lifting of 2000 tons per min.—over 600,000,000 gals. per 24 hours—on a mean lift of about 10 ft. (maximum of 12.5 ft.). (See *Engineering*, 1876.)

The efficiency of centrifugal pumps seems to increase as the size of pump

increases, approximately as follows: A 2" pump (this designation meaning always the size of discharge-outlet in inches of diameter), giving an efficiency of 38%, a 3" pump 45%, and a 4" pump 52%, a 5" pump 60%, and a 6" pump 64% efficiency.

### Tests of Centrifugal Pumps.

**Vanes of Centrifugal Pumps.**—For forms of pump vanes, see paper by W. O. Webber, Trans. A. S. M. E., ix. 228, and discussion thereon by Profs. Thurston, Wood, and others.

**The Centrifugal Pump used as a Suction Dredge.**—The Andrews centrifugal pump was used by Gen. Gillmore, U. S. A., in 1871, in deepening the channel over the bar at the mouth of the St. John's River, Florida. The pump was a No. 9, with suction and discharge pipes each 9 inches diam. It was driven at 300 revolutions per minute by belt from an engine developing 26 useful horse-power.

Although 200 revolutions of the pump disk per minute will easily raise 3000 gallons of clear water 12 ft. high, through a straight vertical 9-inch pipe, 300 revolutions were required to raise 2500 gallons of sand and water 11 ft. high, through two inclined suction-pipes having two turns each, discharged through a pipe having one turn.

The proportion of sand that can be pumped depends greatly upon its specific gravity and fineness. The calcareous and argillaceous sands flow more freely than the silicious, and fine sands are less liable to choke the pipe than those that are coarse. When working at high speed, 50% to 55% of sand can be raised through a straight vertical pipe, giving for every 10 cubic yards of material discharged 5 to 5 $\frac{1}{2}$  cubic yards of compact sand. With the appliances used on the St. John's bar, the proportion of sand seldom exceeded 45%, generally ranging from 30% to 35% when working under the most favorable conditions.

In pumping 2500 gallons, or 12.6 cubic yards of sand and water per minute, there would therefore be obtained from 3.7 to 4.3 cubic yards of sand. During the early stages of the work, before the teeth under the drag had been properly arranged to aid the flow of sand into the pipes, the yield was considerably below this average. (From catalogue of Jos. Edwards & Co., Mfrs. of the Andrews Pump, New York.)

### DUTY TRIALS OF PUMPING-ENGINES.

A committee of the A. S. M. E. (Trans., xii. 530) reported in 1891 on a standard method of conducting duty trials. Instead of the old unit of duty of foot-pounds of work per 100 lbs. of coal used, the committee recommend a new unit, foot-pounds of work per million heat-units furnished by the boiler. The variations in quality of coal make the old standard unfit as a basis of duty ratings. The new unit is the precise equivalent of 100 lbs. of coal in cases where each pound of coal imparts 10,000 heat-units to the water in the boiler, or where the evaporation is  $10,000 \div 965.7 = 10.355$  lbs. of water from and at 212° per pound of fuel. This evaporative result is readily obtained from all grades of Cumberland bituminous coal, used in horizontal return tubular boilers, and, in many cases, from the best grades of anthracite coal.

The committee also recommend that the work done be determined by plunger displacement, after making a test for leakage, instead of by measurement of flow by weirs or other apparatus, but advise the use of such apparatus when practicable for obtaining additional data. The following extracts are taken from the report. When important tests are to be made the complete report should be consulted.

The necessary data having been obtained, the duty of an engine, and other quantities relating to its performance, may be computed by the use of the following formulæ:

$$\begin{aligned} 1. \text{ Duty} &= \frac{\text{Foot-pounds of work done}}{\text{Total number of heat-units consumed}} \times 1,000,000 \\ &= \frac{A(P \pm p + s) \times L \times N}{H} \times 1,000,000 \text{ (foot-pounds).} \end{aligned}$$

$$2. \text{ Percentage of leakage} = \frac{C \times 144}{A \times L \times N} \times 100 \text{ (per cent).}$$

$$\begin{aligned} 3. \text{ Capacity} &= \text{number of gallons of water discharged in 24 hours} \\ &= \frac{A \times L \times N \times 7.4805 \times 24}{D \times 144} = \frac{A \times L \times N \times 1.24675}{D} \text{ (gallons).} \end{aligned}$$

4. Percentage of total frictions,

$$\begin{aligned} &= \left[ \frac{\text{I.H.P.} - \frac{A(P \pm p + s) \times L \times N}{D \times 60 \times 33,000}}{\text{I.H.P.}} \right] \times 100 \\ &= \left[ 1 - \frac{A(P \pm p + s) \times L \times N}{A_s \times \text{M.E.P.} \times L_s \times N_s} \right] \times 100 \text{ (per cent);} \end{aligned}$$

or, in the usual case, where the length of the stroke and number of strokes of the plunger are the same as that of the steam-piston, this last formula becomes:

$$\text{Percentage of total frictions} = \left[ 1 - \frac{A(P \pm p + s)}{A_s \times \text{M.E.P.}} \right] \times 100 \text{ (per cent).}$$

In these formulæ the letters refer to the following quantities:

$A$  = Area, in square inches, of pump plunger or piston, corrected for area of piston rod or rods;

$P$  = Pressure, in pounds per square inch, indicated by the gauge on the force main;

$p$  = Pressure, in pounds per square inch, corresponding to indication of the vacuum-gauge on suction-main (or pressure-gauge, if the suction-pipe is under a head). The indication of the vacuum-gauge, in inches of mercury, may be converted into pounds by dividing it by 2.035;

$s$  = Pressure, in pounds per square inch, corresponding to distance between the centres of the two gauges. The computation for this pressure is made by multiplying the distance, expressed in feet, by the weight of one cubic foot of water at the temperature of the pump-well, and dividing the product by 144;

$L$  = Average length of stroke of pump-plunger, in feet;

$N$  = Total number of single strokes of pump-plunger made during the trial;

$A_s$  = Area of steam-cylinder, in square inches, corrected for area of piston-rod. The quantity  $A_s \times \text{M.E.P.}$ , in an engine having more than one cylinder, is the sum of the various quantities relating to the respective cylinders;

$L_s$  = Average length of stroke of steam-piston, in feet;

$N_s$  = Total number of single strokes of steam-piston during trial;

$\text{M.E.P.}$  = Average mean effective pressure, in pounds per square inch, measured from the indicator-diagrams taken from the steam-cylinder;

$\text{I.H.P.}$  = Indicated horse-power developed by the steam-cylinder;

$C$  = Total number of cubic feet of water which leaked by the pump-plunger during the trial, estimated from the results of the leakage test;

$D$  = Duration of trial in hours;

$H =$  Total number of heat-units (B. T. U.) consumed by engine = weight of water supplied to boiler by main feed-pump  $\times$  total heat of steam of boiler pressure reckoned from temperature of main feed-water + weight of water supplied by jacket-pump  $\times$  total heat of steam of boiler-pressure reckoned from temperature of jacket-water + weight of any other water supplied  $\times$  total heat of steam reckoned from its temperature of supply. The total heat of the steam is corrected for the moisture or superheat which the steam may contain. No allowance is made for water added to the feed-water, which is derived from any source, except the engine or some accessory of the engine. Heat added to the water by the use of a flue-heater at the boiler is not to be deducted. Should heat be abstracted from the flue by means of a steam reheater connected with the intermediate receiver of the engine, this heat must be included in the total quantity supplied by the boiler.

**Leakage Test of Pump.**—The leakage of an inside plunger (the only type which requires testing) is most satisfactorily determined by making the test with the cylinder-head removed. A wide board or plank may be temporarily bolted to the lower part of the end of the cylinder, so as to hold back the water in the manner of a dam, and an opening made in the temporary head thus provided for the reception of an overflow-pipe. The plunger is blocked at some intermediate point in the stroke (or, if this position is not practicable, at the end of the stroke), and the water from the force main is admitted at full pressure behind it. The leakage escapes through the overflow-pipe, and it is collected in barrels and measured. The test should be made, if possible, with the plunger in various positions.

In the case of a pump so planned that it is difficult to remove the cylinder-head, it may be desirable to take the leakage from one of the openings which are provided for the inspection of the suction-valves, the head being allowed to remain in place.

It is assumed that there is a practical absence of valve leakage. Examination for such leakage should be made, and if it occurs, and it is found to be due to disordered valves, it should be remedied before making the plunger test. Leakage of the discharge valves will be shown by water passing down into the empty cylinder at either end when they are under pressure. Leakage of the suction-valves will be shown by the disappearance of water which covers them.

If valve leakage is found which cannot be remedied the quantity of water thus lost should also be tested. One method is to measure the amount of water required to maintain a certain pressure in the pump cylinder when this is introduced through a pipe temporarily erected, no water being allowed to enter through the discharge valves of the pump.

**Table of Data and Results.**—In order that uniformity may be secured, it is suggested that the data and results, worked out in accordance with the standard method, be tabulated in the manner indicated in the following scheme :

DUTY TRIAL OF ENGINE.

DIMENSIONS.

1. Number of steam-cylinders.....
2. Diameter of steam-cylinders..... ins.
3. Diameter of piston-rods of steam-cylinders..... ins.
4. Nominal stroke of steam-pistons..... ft.
5. Number of water-plungers .....
6. Diameter of plungers..... ins.
7. Diameter of piston-rods of water-cylinders..... ins.
8. Nominal stroke of plungers..... ft.
9. Net area of steam-pistons..... sq. ins.
10. Net area of plungers..... sq. ins.
11. Average length of stroke of steam-pistons during trial..... ft.
12. Average length of stroke of plungers during trial..... ft.

(Give also complete description of plant.)

TEMPERATURES.

13. Temperature of water in pump-well..... degs.
14. Temperature of water supplied to boiler by main feed-pump.. degs.
15. Temperature of water supplied to boiler from various other sources..... degs.

## FEED-WATER.

16. Weight of water supplied to boiler by main feed-pump..... lbs.  
 17. Weight of water supplied to boiler from various other sources. lbs.  
 18. Total weight of feed-water supplied from all sources..... lbs.

## PRESSURES.

19. Boiler pressure indicated by gauge..... lbs.  
 20. Pressure indicated by gauge on force main..... lbs.  
 21. Vacuum indicated by gauge on suction main..... ins.  
 22. Pressure corresponding to vacuum given in preceding line..... lbs.  
 23. Vertical distance between the centres of the two gauges..... ins.  
 24. Pressure equivalent to distance between the two gauges..... lbs.

## MISCELLANEOUS DATA.

25. Duration of trial ..... hrs.  
 26. Total number of single strokes during trial.....  
 27. Percentage of moisture in steam supplied to engine, or number of degrees of superheating..... % or deg.  
 28. Total leakage of pump during trial, determined from results of leakage test ..... lbs.  
 29. Mean effective pressure, measured from diagrams taken from steam-cylinders ..... M.E.P.

## PRINCIPAL RESULTS.

30. Duty..... ft. lbs.  
 31. Percentage of leakage..... %  
 32. Capacity..... gals.  
 33. Percentage of total friction..... %

## ADDITIONAL RESULTS.

34. Number of double strokes of steam-piston per minute .....  
 35. Indicated horse-power developed by the various steam-cylinders I.H.P.  
 36. Feed-water consumed by the plant per hour. .... lbs.  
 37. Feed-water consumed by the plant per indicated horse-power per hour, corrected for moisture in steam. .... lbs.  
 38. Number of heat units consumed per indicated horse-power per hour..... B.T.U.  
 39. Number of heat units consumed per indicated horse-power per minute..... B.T.U.  
 40. Steam accounted for by indicator at cut-off and release in the various steam-cylinders..... lbs.  
 41. Proportion which steam accounted for by indicator bears to the feed-water consumption ...  
 42. Number of double strokes of pump per minute ..  
 43. Mean effective pressure, measured from pump diagrams ..... M.E.P.  
 44. Indicated horse-power exerted in pump-cylinders..... I.H.P.  
 45. Work done (or duty) per 100 lbs. of coal ..... ft. lbs.

## SAMPLE DIAGRAM TAKEN FROM STEAM-CYLINDERS.

(Also, if possible, full measurement of the diagrams, embracing pressures at the initial point, cut-off, release, and compression; also back pressure, and the proportions of the stroke completed at the various points noted.)

## SAMPLE DIAGRAM TAKEN FROM PUMP-CYLINDERS.

These are not necessary to the main object, but it is desirable to give them.

## DATA AND RESULTS OF BOILER TEST.

(In accordance with the scheme recommended by the Boiler-test Committee of the Society.)

**VACUUM PUMPS--AIR-LIFT PUMP.**

**The Pulsometer.**—In the pulsometer the water is raised by suction into the pump-chamber by the condensation of steam within it, and is then forced into the delivery-pipe by the pressure of a new quantity of steam on the surface of the water. Two chambers are used which work alternately, one raising while the other is discharging.

*Test of a Pulsometer.*—A test of a pulsometer is described by De Volson Wood in Trans. A. S. M. E. xiii. It had a  $3\frac{1}{2}$ -inch suction-pipe, stood 40 in. high, and weighed 695 lbs.

The steam-pipe was 1 inch in diameter. A throttle was placed about 2 feet

from the pump, and pressure gauges placed on both sides of the throttle, and a mercury well and thermometer placed beyond the throttle. The wire drawing due to throttling caused superheating.

The pounds of steam used were computed from the increase of the temperature of the water in passing through the pump.

Pounds of steam  $\times$  loss of heat = lbs. of water sucked in  $\times$  increase of temp.

The loss of heat in a pound of steam is the total heat in a pound of saturated steam as found from "steam tables" for the given pressure, plus the heat of superheating, minus the temperature of the discharged water ; or

$$\text{Pounds of steam} = \frac{\text{lbs. water} \times \text{increase of temp.}}{H - 0.48t - T.}$$

The results for the four tests are given in the following table :

Data and Results.	Number of Test.			
	1	2	3	4
Strokes per minute .....	71	60	57	64
Steam press. in pipe before throttl'g	114	110	127	104.3
Steam press. in pipe after throttl'g	19	30	43.8	26.1
Steam temp. after throttling, deg. F.	270.4	277	309.0	270.1
Steam am't of superheat'g, deg. F.	3.1	3.4	17.4	1.4
Steam used as det'd from temp., lbs.	1617	931	1518	1019.9
Water pumped, lbs. ....	404,786	186,362	228,425	248,053
Water temp. before entering pump,	75.15	80.6	76.3	70.25
Water temp., rise of.....	4.47	5.5	7.49	4.55
Water head by gauge on lift, ft....	29.90	54.05	54.05	29.90
Water head by gauge on suction...	12.26	12.26	19.67	19.67
Water head by gauge, total (H)....	42.16	66.31	73.72	49.57
Water head by measure, total (h)	32.8	57.80	66.6	41.66
Coeff. of friction of plant (h) $\div$ (H)	0.777	0.877	0.911	0.839
Efficiency of pulsometer.....	0.012	0.0155	0.0126	0.0138
Effic. of plant exclusive of boiler...	0.0093	0.0136	0.0115	0.0116
Effic. of plant if that of boiler be 0.7	0.0065	0.0095	0.0080	0.0081
Duty, if 1 lb. evaporates 10 lbs. water	10,511,400	13,391,000	11,059,000	12,036,300

Of the two tests having the highest lift (54.05 ft.), that was more efficient which had the smaller suction (12.26 ft.), and this was also the most efficient of the four tests. But, on the other hand, the other two tests having the same lift (29.9 ft.), that was the more efficient which had the greater suction (19.67), so that no law in this regard was established. The pressures used, 19, 30, 43.8, 26.1, follow the order of magnitude of the total heads, but are not proportional thereto. No attempt was made to determine what pressure would give the best efficiency for any particular head. The pressure used was intrusted to a practical runner, and he judged that when the pump was running regularly and well, the pressure then existing was the proper one. It is peculiar that, in the first test, a pressure of 19 lbs. of steam should produce a greater number of strokes and pump over 50% more water than 26.1 lbs., the lift being the same, as in the fourth experiment.

Chas. E. Emery in discussion of Prof. Wood's paper says, referring to tests made by himself and others at the Centennial Exhibition in 1876 (see Report of the Judges, Group xx.), that a vacuum-pump tested by him in 1871 gave a duty of 4.7 millions; one tested by J. F. Flagg, at the Cincinnati Exposition in 1875, gave a maximum duty of 3.25 millions. Several vacuum and small steam-pumps, compared later on the same basis, were reported to have given duties of 10 to 11 millions, the steam-pumps doing no better than the vacuum-pumps. Injectors, when used for lifting water not required to be heated, have an efficiency of 2 to 5 millions; vacuum-pumps vary generally between 3 and 10; small steam-pumps between 8 and 15; larger steam-pumps, between 15 and 30, and pumping-engines between 30 and 140 millions.

A very high record of test of a pulsometer is given in *Eng'g*, Nov. 24, 1893, p. 639, viz.: Height of suction 11.27 ft.; total height of lift, 102.6 ft.; horizontal length of delivery-pipe, 118 ft.; quantity delivered per hour, 26,188 British gallons. Weight of steam used per H. P. per hour, 92.76 lbs.; work

done per pound of steam 21,345 foot-pounds, equal to a duty of 21,345,000 foot-pounds per 100 lbs. of coal, if 10 lbs of steam were generated per pound of coal.

**The Jet-pump.**—This machine works by means of the tendency of a stream or jet of fluid to drive or carry contiguous particles of fluid along with it. The water-jet pump, in its present form, was invented by Prof. James Thomson, and first described in 1852. In some experiments on a small scale as to the efficiency of the jet-pump, the greatest efficiency was found to take place when the depth from which the water was drawn by the suction-pipe was about nine tenths of the height from which the water fell to form the jet; the flow up the suction-pipe being in that case about one fifth of that of the jet, and the efficiency, consequently,  $9/10 \times 1/5 = 0.18$ . This is but a low efficiency; but it is probable that it may be increased by improvements in proportions of the machine. (Rankine, S. E.)

**The Injector** when used as a pump has a very low efficiency. (See Injectors, under Steam-boilers.)

**Air-lift Pump.**—The air-lift pump consists of a vertical water-pipe with its lower end submerged in a well, and a smaller pipe delivering air into it at the bottom. The rising column in the pipe consists of air mingled with water, the air being in bubbles of various sizes, and is therefore lighter than a column of water of the same height; consequently the water in the pipe is raised above the level of the surrounding water. This method of raising water was proposed as early as 1797, by Loescher, of Freiberg, and was mentioned by Collon in lectures in Paris in 1876, but its first practical application probably was by Werner Siemens in Berlin in 1885. Dr. J. G. Pohle experimented on the principle in California in 1886, and U. S. patents on apparatus involving it were granted to Pohle and Hill in the same year. A paper describing tests of the air-lift pump made by Randall, Browne and Behr was read before the Technical Society of the Pacific Coast in Feb. 1890.

The diameter of the pump-column was 3 in., of the air-pipe 0.9 in., and of the air-discharge nozzle  $5/8$  in. The air-pipe had four sharp bends and a length of 35 ft. plus the depth of submersion.

The water was pumped from a closed pipe-well (55 ft. deep and 10 in. in diameter). The efficiency of the pump was based on the least work theoretically required to compress the air and deliver it to the receiver. If the efficiency of the compressor be taken at 70%, the efficiency of the pump and compressor together would be 70% of the efficiency found for the pump alone.

For a given submersion ( $h$ ) and lift ( $H$ ), the ratio of the two being kept within reasonable limits, ( $H$ ) being not much greater than ( $h$ ), the efficiency was greatest when the pressure in the receiver did not greatly exceed the head due to the submersion. The smaller the ratio  $H \div h$ , the higher was the efficiency.

The pump, as erected, showed the following efficiencies:

For $H \div h =$	0.5	1.0	1.5	2.0
Efficiency =	50%	40%	30%	25%

The fact that there are absolutely no moving parts makes the pump especially fitted for handling dirty or gritty water, sewage, mine water, and acid or alkali solutions in chemical or metallurgical works.

In Newark, N. J., pumps of this type are at work having a total capacity of 1,000,000 gallons daily, lifting water from three 8-in. artesian wells. The Newark Chemical Works use an air-lift pump to raise sulphuric acid of 1.72° gravity. The Colorado Central Consolidated Mining Co., in one of its mines at Georgetown, Colo., lifts water in one case 250 ft., using a series of lifts.

For a full account of the theory of the pump, and details of the tests above referred to, see *Eng'g News*, June 8, 1893.

### THE HYDRAULIC RAM.

**Efficiency.**—The hydraulic ram is used where a considerable flow of water with a moderate fall is available, to raise a small portion of that flow to a height exceeding that of the fall. The following are rules given by Eytelwein as the results of his experiments (from Rankine):

Let  $Q$  be the whole supply of water in cubic feet per second, of which  $q$  is lifted to the height  $h$  above the pond, and  $Q - q$  runs to waste at the depth  $H$  below the pond;  $L$ , the length of the supply-pipe, from the pond to the waste-clack;  $D$ , its diameter in feet; then

$$D = \sqrt{(1.63Q)}; \quad L = H + h + \frac{h}{H} \times 2 \text{ feet};$$

Volume of air vessel = volume of feed pipe;

Efficiency,  $\frac{qh}{(Q-q)H} = 1.12 - 0.2 \sqrt{\frac{h}{H}}$  when  $\frac{h}{H}$  does not exceed 20.

or

$1 \div \left(1 + \frac{h}{10H}\right)$  nearly, when  $\frac{h}{H}$  does not exceed 12.

D'Aubuisson gives  $\frac{q(H+h)}{QH} = 1.42 - .28 \sqrt{\frac{h}{H}}$

Clark, using five sixths of the values given by D'Aubuisson's formula, gives:

Ratio of lift to fall....	4	6	8	10	12	14	16	18	20	22	24	26
Efficiency per cent....	72	61	52	44	37	31	25	19	14	9	4	0

Prof. R. C. Carpenter (*Eng'g Mechanics*, 1894) reports the results of four tests of a ram constructed by Rumsey & Co., Seneca Falls. The ram was fitted for pipe connection for 1¼-inch supply and ½-inch discharge. The supply-pipe used was 1½ inches in diameter, about 50 feet long, with 3 elbows, so that it was equivalent to about 65 feet of straight pipe, so far as resistance is concerned. Each run was made with a different stroke for the waste or clack-valve, the supply and delivery head being constant; the object of the experiment was to find that stroke of clack-valve which would give the highest efficiency.

Length of stroke, per cent.....	100	80	60	46
Number of strokes per minute.....	52	56	61	66
Supply head, feet of water.....	5.67	5.77	5.58	5.65
Delivery head, feet of water.....	19.75	19.75	19.75	19.75
Total water pumped, pounds.....	297	296	301	297.5
Total water supplied, pounds.....	1615	1567	1518	1455.5
Efficiency, per cent.....	64.9	66	74.9	70

The efficiency, 74.9, the highest realized, was obtained when the clack-valve travelled a distance equal to 60% of its full stroke, the full travel being 15/16 of one inch.

**Quantity of Water Delivered by the Hydraulic Ram.**  
(Chadwick Lead Works.)—From 80 to 100 feet conveyance, one seventh of supply from spring can be discharged at an elevation five times as high as the fall to supply the ram; or, one fourteenth can be raised and discharged say ten times as high as the fall applied.

Water can be conveyed by a ram 3000 feet, and elevated 200 feet. The drive-pipe is from 25 to 50 feet long.

The following table gives the capacity of several sizes of rams, the dimensions of the pipes to be used, and the size of the spring or brook to which they are adapted:

Size of Ram.	Quantity of Water Furnished per Min. by the Spring or Brook to which the Ram is Adapted.	Caliber of Pipes.		Weight of Pipe (Lead), if Wrought Iron, then of Ordinary Weight.		
		Drive.	Discharge.	Drive-pipe for head or fall not over 10 ft.	Discharge-pipe for not over 50 ft. rise.	Discharge-pipe for over 50 ft. and not exceeding 100 ft. in height.
No.	Gals. per min.	inch.	inch.	per foot.	per foot.	per foot.
2	¾ to 2	¾	¾	2 lbs.	10 ozs.	1 lb.
3	1½ " 4	1	½	3 "	12 "	1 " 4 ozs.
4	3 " 7	1¼	½	5 "	12 "	1 " 4 ozs.
5	6 " 14	2	¾	8 "	1 lb. 4 "	2 "

**HYDRAULIC-PRESSURE TRANSMISSION.**

Water under high pressure (700 to 2000 lbs. per square inch and upwards) affords a very satisfactory method of transmitting power to a distance, especially for the movement of heavy loads at small velocities, as by cranes and elevators. The system consists usually of one or more pumps capable of developing the required pressure; accumulators, which are vertical cylinders with heavily-weighted plungers passing through stuffing-boxes in the upper end, by which a quantity of water may be accumulated at the pressure to which the plunger is weighted; the distributing-pipes; and the presses, cranes, or other machinery to be operated.

The earliest important use of hydraulic pressure probably was in the Bramah hydraulic press, patented in 1796. Sir W. G. Armstrong in 1846 was one of the pioneers in the adaptation of the hydraulic system to cranes. The use of the accumulator by Armstrong led to the extended use of hydraulic machinery. Recent developments and applications of the system are largely due to Ralph Tweddell, of London, and Sir Joseph Whitworth. Sir Henry Bessemer, in his patent of May 13, 1856, No. 1292, first suggested the use of hydraulic pressure for compressing steel ingots while in the fluid state.

**The Gross Amount of Energy** of the water under pressure stored in the accumulator, measured in foot-pounds, is its volume in cubic feet  $\times$  its pressure in pounds per square foot. The horse-power of a given quantity steadily flowing is  $H.P. = \frac{144pQ}{550} = .2618pQ$ , in which  $Q$  is the quantity flowing in cubic feet per second and  $p$  the pressure in pounds per square inch.

The loss of energy due to velocity of flow in the pipe is calculated as follows (R. G. Blaine, *Eng'g*, May 22 and June 5, 1891):

According to D'Arcy, every pound of water loses  $\frac{\lambda 4L}{D}$  times its kinetic energy, or energy due to its velocity, in passing along a straight pipe  $L$  feet in length and  $D$  feet diameter, where  $\lambda$  is a variable coefficient. For clean cast-iron pipes it may be taken as  $\lambda = .005 \left( 1 + \frac{1}{12D} \right)$ , or for diameter in inches =  $d$ .

$d = \frac{1}{2}$	1	2	3	4	5	6	7	8	9	10	12
$\lambda = .015$	.01	.0075	.00667	.00625	.006	.00583	.00571	.00563	.00556	.0055	.00543

The loss of energy per minute is  $60 \times 62.36Q \times \frac{\lambda 4L}{D} \frac{v^2}{2g}$ , and the horse-power wasted in the pipe is  $W = \frac{.6363\lambda L(H.P.)^3}{p^3 D^5}$ , in which  $\lambda$  varies with the diameter as above.  $p$  = pressure at entrance in pounds per square inch. Values of  $.6363\lambda$  for different diameters of pipe in inches are:

$d = \frac{1}{2}$	1	2	3	4	5	6	7	8	9	10	12
.00954	.00636	.00477	.00424	.00398	.00382	.00371	.00363	.00358	.00353	.00350	.00345

**Efficiency of Hydraulic Apparatus.**—The useful effect of a direct hydraulic plunger or ram is usually taken at 93%. The following is given as the efficiency of a ram with chain-and-pulley multiplying gear properly proportioned and well lubricated:

Multiplying....	2 to 1	4 to 1	6 to 1	8 to 1	10 to 1	12 to 1	14 to 1	16 to 1
Efficiency %....	80	76	72	67	63	59	54	50

With large sheaves, small steel pins, and wire rope for multiplying gear the efficiency has been found as high as 66% for a multiplication of 20 to 1.

Henry Adams gives the following formula for effective pressure in cranes and hoists:

$P$  = accumulator pressure in pounds per square inch;  
 $m$  = ratio of multiplying power;  
 $E$  = effective pressure in pounds per square inch, including all allowances for friction;

$$E = P(.84 - .02m).$$

J. E. Tuit (*Eng'g*, June 15, 1888) describes some experiments on the friction of hydraulic jacks from  $3\frac{1}{4}$  to  $13\frac{5}{8}$ -inch diameter, fitted with cupped leather packings. The friction loss varied from 5.6% to 18.8% according to the condition of the leather, the distribution of the load on the ram, etc. The friction increased considerably with eccentric loads. With hemp packing a plunger, 14-inch diameter, showed a friction loss of from 11.4% to 3.4%, the load being central, and from 15.0% to 7.6% with eccentric load, the percentage of loss decreasing in both cases with increase of load.

**Thickness of Hydraulic Cylinders.**—From a table used by Sir W. G. Armstrong we take the following, for cast-iron cylinders, for an interior pressure of 1000 lbs. per square inch:

Diam. of cylinder, inches..	2	4	6	8	10	12	16	20	24
Thickness, inches.....	0.832	1.146	1.552	1.875	2.222	2.578	3.19	3.69	4.11

For any other pressure multiply by the ratio of that pressure to 1000. These figures correspond nearly to the formula  $t = 0.175d + 0.48$ , in which  $t$  = thickness and  $d$  = diameter in inches, up to 16 inches diameter, but for 20 inches diameter the addition 0.48 is reduced to 0.19 and at 24 inches it disappears. For formulæ for thick cylinders see page 287, *ante*.

Cast iron should not be used for pressures exceeding 2000 lbs. per square inch. For higher pressures steel castings or forged steel should be used. For working pressures of 750 lbs. per square inch the test pressure should be 2500 lbs. per square inch, and for 1500 lbs. the test pressure should not be less than 3500 lbs.

**Speed of Hoisting by Hydraulic Pressure.**—The maximum allowable speed for warehouse cranes is 6 feet per second; for platform cranes 4 feet per second; for passenger and wagon hoists, heavy loads, 2 feet per second. The maximum speed under any circumstances should never exceed 10 feet per second.

**The Speed of Water Through Valves** should never be greater than 100 feet per second.

**Speed of Water Through Pipes.**—Experiments on water at 1600 lbs. pressure per square inch flowing into a flanging-machine ram, 20-inch diameter, through a  $\frac{1}{2}$ -inch pipe contracted at one point to  $\frac{1}{4}$ -inch, gave a velocity of 114 feet per second in the pipe, and 456 feet at the reduced section. Through a  $\frac{1}{2}$ -inch pipe reduced to  $\frac{3}{8}$ -inch at one point the velocity was 213 feet per second in the pipe and 381 feet at the reduced section. In a  $\frac{1}{2}$ -inch pipe without contraction the velocity was 355 feet per second.

For many of the above notes the author is indebted to Mr. John Platt, consulting engineer, of New York.

**High-pressure Hydraulic Presses in Iron-works** are described by R. M. Daelen, of Germany, in *Trans. A. I. M. E.* 1892. The following distinct arrangements used in different systems of high-pressure hydraulic work are discussed and illustrated:

1. Steam-pump, with fly-wheel and accumulator.
2. Steam-pump, without fly-wheel and with accumulator.
3. Steam-pump, without fly-wheel and without accumulator.

In these three systems the valve-motion of the working press is operated in the high-pressure column. This is avoided in the following:

4. Single-acting steam-intensifier without accumulator.
5. Steam-pump with fly-wheel, without accumulator and with pipe-circuit.
6. Steam-pump with fly-wheel, without accumulator and without pipe-circuit.

The disadvantages of accumulators are thus stated: The weighted plungers which formerly served in most cases as accumulators, cause violent shocks in the pipe-line when changes take place in the movement of the water, so that in many places, in order to avoid bursting from this cause, the pipes are made exclusively of forged and bored steel. The seats and cones of the metallic valves are cut by the water (at high speed), and in such cases only the most careful maintenance can prevent great losses of power.

**Hydraulic Power in London.**—The general principle involved is pumping water into mains laid in the streets, from which service-pipes are carried into the houses to work lifts or three-cylinder motors when rotatory power is required. In some cases a small Pelton wheel has been tried, working under a pressure of over 700 lbs. on the square inch. Over 55 miles of hydraulic mains are at present laid (1892).

The reservoir of power consists of capacious accumulators, loaded to a pressure of 800 lbs. per square inch, thus producing the same effect as if large supply-tanks were placed at 1700 feet above the street-level. The water is taken from the Thames or from wells, and all sediment is removed therefrom by filtration before it reaches the main engine-pumps.

There are over 1750 machines at work, and the supply is about 6,500,000 gallons per week.

It is essential that the water used should be clean. The storage-tank extends over the whole boiler-house and coal-store. The tank is divided, and a certain amount of mud is deposited here. It then passes through the surface condenser of the engines, and it is turned into a set of filters, eight in number. The body of the filter is a cast-iron cylinder, containing a layer of

granular filtering material resting upon a false bottom; under this is the distributing arrangement, affording passage for the air, and under this the real bottom of the tank. The dirty water is supplied to the filters from an overhead tank. After passing through the filters the clean effluent is pumped into the clean-water tank, from which the pumping-engines derive their supply. The cleaning of the filters, which is done at intervals of 24 hours, is effected so thoroughly *in situ* that the filtering material never requires to be removed.

The engine-house contains six sets of triple-expansion engines. The cylinders are 15-inch, 22-inch, 36-inch  $\times$  24-inch. Each cylinder drives a single plunger-pump with a 5-inch ram, secured directly to the cross-head, the connecting-rod being double to clear the pump. The boiler-pressure is 150 lbs. on the square inch. Each pump will deliver 300 gallons of water per minute under a pressure of 800 lbs. to the square inch, the engines making about 61 revolutions per minute. This is a high velocity, considering the heavy pressure; but the valves work silently and without perceptible shock.

The consumption of steam is 14.1 pounds per horse per hour.

The water delivered from the main pumps passes into the accumulators. The rams are 20 inches in diameter, and have a stroke of 23 feet. They are each loaded with 110 tons of slag, contained in a wrought-iron cylindrical box suspended from a cross-head on the top of the ram.

One of the accumulators is loaded a little more heavily than the other, so that they rise and fall successively; the more heavily loaded actuates a stop-valve on the main steam-pipe. If the engines supply more water than is wanted, the lighter of the two rams first rises as far as it can go; the other then ascends, and when it has nearly reached the top, shuts off steam and checks the supply of water automatically.

The mains in the public streets are so constructed and laid as to be perfectly trustworthy and free from leakage.

Every pipe and valve used throughout the system is tested to 2500 lbs. per square inch before being placed on the ground and again tested to a reduced pressure in the trenches to insure the perfect tightness of the joints. The jointing material used is gutta-percha.

The average rate obtained by the company is about 3 shillings per thousand gallons. The principal use of the power is for intermittent work in cases where direct pressure can be employed, as, for instance, passenger elevators, cranes, presses, warehouse hoists, etc.

An important use of the hydraulic power is its application to the extinguishing of fire by means of Greathead's injector hydrant. By the use of these hydrants a continuous fire-engine is available.

**Hydraulic Riveting-machines.**—Hydraulic riveting was introduced in England by Mr. R. H. Tweddell. Fixed riveters were first used about 1868. Portable riveting-machines were introduced in 1872.

The riveting of the large steel plates in the Forth Bridge was done by small portable machines working with a pressure of 1000 lbs. per square inch. In exceptional cases 3 tons per inch was used. (Proc. Inst. M. E., May, 1889.)

An application of hydraulic pressure invented by Andrew Higginson, of Liverpool, dispenses with the necessity of accumulators. It consists of a three-throw pump driven by shafting or worked by steam, and depends partially upon the work accumulated in a heavy fly-wheel. The water in its passage from the pumps and back to them is in constant circulation at a very feeble pressure, requiring a minimum of power to preserve the tube of water ready for action at the desired moment, when by the use of a tap the current is stopped from going back to the pumps, and is thrown upon the piston of the tool to be set in motion. The water is now confined, and the driving-belt or steam-engine, supplemented by the momentum of the heavy fly-wheel, is employed in closing up the rivet, or bending or forging the object subjected to its operation.

**Hydraulic Forging.**—In the production of heavy forgings from cast ingots of mild steel it is essential that the mass of metal should be operated on as equally as possible throughout its entire thickness. When employing a steam-hammer for this purpose it has been found that the external surface of the ingot absorbs a large proportion of the sudden impact of the blow, and that a comparatively small effect only is produced on the central portions of the ingot, owing to the resistance offered by the inertia of the mass to the rapid motion of the falling hammer—a disadvantage that is entirely overcome by the slow, though powerful, compression of the hydraulic forging-press, which appears destined to supersede the steam-hammer for the production of massive steel forgings.

In the Allen forging-press the force-pump and the large or main cylinder of the press are in direct and constant communication. There are no intermediate valves of any kind, nor has the pump any clack-valves, but it simply forces its cylinder full of water direct into the cylinder of the press, and receives the same water, as it were, back again on the return stroke. Thus, when both cylinders and the pipe connecting them are full, the large ram of the press rises and falls simultaneously with each stroke of the pump, keeping up a continuous oscillating motion, the ram, of course, travelling the shorter distance, owing to the larger capacity of the press cylinder. (Journal Iron and Steel Institute, 1891. See also illustrated article in "Modern Mechanism," page 668.)

For a very complete illustrated account of the development of the hydraulic forging-press, see a paper by R. H. Tweddell in Proc. Inst. C. E., vol. cxvii. 1893-4.

**Hydraulic Forging-press.**—A 2000-ton forging-press erected at the Couillet forges in Belgium is described in *Eng. and M. Jour.*, Nov. 25, 1893.

The press is composed essentially of two parts—the press itself and the compressor. The compressor is formed of a vertical steam-cylinder and a hydraulic cylinder. The piston-rod of the former forms the piston of the latter. The hydraulic piston discharges the water into the press proper. The distribution is made by a cylindrical balanced valve; as soon as the pressure is released the steam-piston falls automatically under the action of gravity. During its descent the steam passes to the other face of the piston to reheat the cylinder, and finally escapes from the upper end.

When steam enters under the piston of the compressor-cylinder the piston rises, and its rod forces the water into the press proper. The pressure thus exerted on the piston of the latter is transmitted through a cross-head to the forging which is upon the anvil. To raise the cross-head two small single-acting steam-cylinders are used, their piston-rods being connected to the cross-head; steam acts only on the pistons of these cylinders from below. The admission of steam to the cylinders, which stand on top of the press frame, is regulated by the same lever which directs the motions of the compressor. The movement given to the dies is sufficient for all the ordinary purposes of forging.

A speed of 30 blows per minute has been attained. A double press on the same system, having two compressors and giving a maximum pressure of 6000 tons, has been erected in the Krupp works, at Essen.

**The Aiken Intensifier.** (*Iron Age*, Aug. 1890.)—The object of the machine is to increase the pressure obtained by the ordinary accumulator which is necessary to operate powerful hydraulic machines requiring very high pressures, without increasing the pressure carried in the accumulator and the general hydraulic system.

The Aiken Intensifier consists of one outer stationary cylinder and one inner cylinder which moves in the outer cylinder and on a fixed or stationary hollow plunger. When operated in connection with the hydraulic bloom-shear the method of working is as follows: The inner cylinder having been filled with water and connected through the hollow plunger with the hydraulic cylinder of the shear, water at the ordinary accumulator-pressure is admitted into the outer cylinder, which being four times the sectional area of the plunger gives a pressure in the inner cylinder and shear cylinder connected therewith of four times the accumulator-pressure—that is, if the accumulator-pressure is 500 lbs. per square inch the pressure in the intensifier will be 2000 lbs. per square inch.

**Hydraulic Engine driving an Air-compressor and a Forging-hammer.** (*Iron Age*, May 12, 1892.)—The great hammer in Terni, near Rome, is one of the largest in existence. Its falling weight amounts to 100 tons, and the foundation belonging to it consists of a block of cast iron of 1000 tons. The stroke is 16 feet  $4\frac{3}{4}$  inches; the diameter of the cylinder 6 feet  $3\frac{1}{2}$  inches; diameter of piston-rod  $13\frac{3}{4}$  inches; total height of the hammer, 62 feet 4 inches. The power to work the hammer, as well as the two cranes of 100 and 150 tons respectively, and other auxiliary appliances belonging to it, is furnished by four air-compressors coupled together and driven directly by water-pressure engines, by means of which the air is compressed to 73.5 pounds per square inch. The cylinders of the water-pressure engines, which are provided with a bronze lining, have a  $13\frac{3}{4}$ -inch bore. The stroke is  $47\frac{3}{4}$  inches, with a pressure of water on the piston amounting to 264.6 pounds per square inch. The compressors are bored out to  $31\frac{1}{2}$  inches diameter, and have  $47\frac{3}{4}$ -inch stroke. Each of the four cylinders requires a power equal to 280 horse-power. The compressed air is de-

livered into huge reservoirs, where a uniform pressure is kept up by means of a suitable water-column.

**The Hydraulic Forging Plant at Bethlehem, Pa.,** is described in a paper by R. W. Davenport, read before the Society of Naval Engineers and Marine Architects, 1893. It includes two hydraulic forging-presses complete, with engines and pumps, one of 1500 and one of 4500 tons capacity, together with two Whitworth hydraulic travelling forging-cranes and other necessary appliances for each press; and a complete fluid-compression plant, including a press of 7000 tons capacity and a 125 ton hydraulic travelling crane for serving it (the upper and lower heads of this press weighing respectively about 135 and 120 tons).

A new forging-press has been designed by Mr. John Fritz, for the Bethlehem Works, of 14,000 tons capacity, to be run by engines and pumps of 15,000 horse-power. The plant is served by four open-hearth steel furnaces of a united capacity of 120 tons of steel per heat.

Bodmer, London, 1889; Robinson's "Hydraulic Power and Hydraulic Machinery," London, 1888; Colyer's "Hydraulic Steam, and Hand-power Lifting and Pressing Machinery," London, 1881. See also *Engineering* (London), Aug. 1, 1884, p. 99, March 13, 1885, p. 262; May 22 and June 5, 1891, pp. 612, 665; Feb. 19, 1892, p. 25; Feb. 10, 1893, p. 170.

## FUEL.

**Theory of Combustion of Solid Fuel.** (From Rankine, somewhat altered.)—The ingredients of every kind of fuel commonly used may be thus classed: (1) Fixed or free carbon, which is left in the form of charcoal or coke after the volatile ingredients of the fuel have been distilled away. These ingredients burn either wholly in the solid state ( $C$  to  $CO_2$ ), or part in the solid state and part in the gaseous state ( $CO + O = CO_2$ ), the latter part being first dissolved by previously formed carbonic acid by the reaction  $CO_2 + C = 2CO$ . Carbonic oxide,  $CO$ , is produced when the supply of air to the fire is insufficient.

(2) Hydrocarbons, such as olefiant gas, pitch, tar, naphtha, etc., all of which must pass into the gaseous state before being burned.

If mixed on their first issuing from amongst the burning carbon with a large quantity of hot air, these inflammable gases are completely burned with a transparent blue flame, producing carbonic acid and steam. When mixed with cold air they are apt to be chilled and pass off unburned. When raised to a red heat, or thereabouts, before being mixed with a sufficient quantity of air for perfect combustion, they disengage carbon in fine powder, and pass to the condition partly of marsh gas, and partly of free hydrogen; and the higher the temperature, the greater is the proportion of carbon thus disengaged.

If the disengaged carbon is cooled below the temperature of ignition before coming in contact with oxygen, it constitutes, while floating in the gas, smoke, and when deposited on solid bodies, soot.

But if the disengaged carbon is maintained at the temperature of ignition, and supplied with oxygen sufficient for its combustion, it burns while floating in the inflammable gas, and forms red, yellow, or white flame. The flame from fuel is the larger the more slowly its combustion is effected. The flame itself is apt to be chilled by radiation, as into the heating surface of a steam-boiler, so that the combustion is not completed, and part of the gas and smoke pass off unburned.

(3) Oxygen or hydrogen either actually forming water, or existing in combination with the other constituents in the proportions which form water. Such quantities of oxygen and hydrogen are to be left out of account in determining the heat generated by the combustion. If the quantity of water actually or virtually present in each pound of fuel is so great as to make its latent heat of evaporation worth considering, that heat is to be deducted from the total heat of combustion of the fuel.

(4) Nitrogen, either free or in combination with other constituents. This substance is simply inert.

(5) Sulphuret of iron, which exists in coal and is detrimental, as tending to cause spontaneous combustion.

(6) Other mineral compounds of various kinds, which are also inert, and form the ash left after complete combustion of the fuel, and also the flinker or glassy material produced by fusion of the ash, which tends to choke the grate.

**Total Heat of Combustion of Fuels.** (Rankine.)—The following table shows the total heat of combustion with oxygen of one pound of each of the substances named in it, in British thermal units, and also in lbs. of water evaporated from 212°. It also shows the weight of oxygen required to combine with each pound of the combustible and the weight of air necessary in order to supply that oxygen. The quantities of heat are given on the authority of MM. Favre and Silbermann.

Combustible.	Lbs. Oxygen per lb. Combustible.	Lb. Air (about).	Total British Heat-units.	Evaporative Power from 212° F., lbs.
Hydrogen gas.....	8	36	62,032	64.2
Carbon imperfectly burned so as to make carbonic oxide.....	1½	6	4,400	4.55
Carbon perfectly burned so as to make carbonic acid.....	2¾	12	14,500	15.0
Olefiant gas, 1 lb.....	3 3/7	15 3/7	21,344	22.1
Various liquid hydrocarbons, 1 lb.....	.....	.....	from 21,700 to 19,000	from 22½ to 20
Carbonic oxide, as much as is made by the imperfect combustion of 1 lb. of carbon, viz., 2½ lbs.....	1½	6	10,000	10.45

The imperfect combustion of carbon, making carbonic oxide, produces less than one third of the heat which is yielded by the complete combustion.

The total heat of combustion of any compound of hydrogen and carbon is nearly the sum of the quantities of heat which the constituents would produce separately by their combustion. (Marsh-gas is an exception.)

In computing the total heat of combustion of compounds containing oxygen as well as hydrogen and carbon, the following principle is to be observed: When hydrogen and oxygen exist in a compound in the proper proportion to form water (that is, by weight one part of hydrogen to eight of oxygen), these constituents have no effect on the total heat of combustion. If hydrogen exists in a greater proportion, only the surplus of hydrogen above that which is required by the oxygen is to be taken into account.

The following is a general formula (Dulong's) for the total heat of combustion of any compound of carbon, hydrogen, and oxygen:

Let *C*, *H*, and *O* be the fractions of one pound of the compound, which consists respectively of carbon, hydrogen, and oxygen, the remainder being nitrogen, ash, and other impurities. Let *h* be the total heat of combustion of one pound of the compound in British thermal units. Then

$$h = 14,500 \left\{ C + 4.28 \left( H - \frac{O}{8} \right) \right\}.$$

The following table shows the composition of those compounds which are of importance, either as furnishing oxygen for combustion, as entering into the composition, or as being produced by the combustion of fuel:

Names.	Symbol of Chemical Composition.	Proportions of Element by Weight.	Chemical Equivalent by Weight.	Proportions of Elements by Volume.
Air.....	.....	N 77 + O 23	100	N 79 + O 21
Water.....	H <sub>2</sub> O	H 2 + O 16	18	H 2 + O
Ammonia.....	NH <sub>3</sub>	H 3 + N 14	17	H 3 + N
Carbonic oxide.....	CO	C 12 + O 16	28	C + O
Carbonic acid.....	CO <sub>2</sub>	C 12 + O 32	44	C + O 2
Olefiant gas.....	CH <sub>2</sub>	C 12 + H 2	14	C + H 2
Marsh-gas or fire-damp.....	CH <sub>4</sub>	C 12 + H 4	16	C + H 4
Sulphurous acid.....	SO <sub>2</sub>	S 32 + O 32	64	.....
Sulphuretted hydrogen.....	SH <sub>2</sub>	S 32 + H 2	34	.....
Sulphuret of carbon.....	S <sub>2</sub> C	S 64 + C 12	76	.....

Since each lb. of C requires  $2\frac{2}{3}$  lbs. of O to burn it to  $\text{CO}_2$ , and air contains 23% of O, by weight,  $2\frac{2}{3} \div 0.23$  or 11.6 lbs. of air are required to burn 1 lb. of C.

**Analyses of Gases of Combustion.**—The following are selected from a large number of analyses of gases from locomotive boilers, to show the range of composition under different circumstances (P. H. Dudley, Trans. A. I. M. E., iv. 250):

Test.	$\text{CO}_2$	CO	O	N	
1	13.8	2.5	2.5	81.6	No smoke visible.
2	11.5	...	6	82.5	Old fire, escaping gas white, engine working hard.
3	8.5	...	8	83	Fresh fire, much black gas,
4	2.3	...	17.2	80.5	Old fire, damper closed, engine standing still.
5	5.7	....	14.7	79.6	" " smoke white, engine working hard.
6	8.4	1.2	8.4	82	New fire, engine not working hard.
7	12	1	4.4	82.6	Smoke black, engine not working hard.
8	3.4	..	16.8	76.8	" dark, blower on, engine standing still.
9	6	...	13.5	81.5	" white, engine working hard.

In analyses on the Cleveland and Pittsburgh road, in every instance when the smoke was the blackest, there was found the greatest percentage of unconsumed oxygen in the product, showing that something besides the mere presence for oxygen is required to effect the combustion of the volatile carbon of fuels.

J. C. Hoadley (Trans. A. S. M. E., vi. 749) found as the mean of a great number of analyses of flue gases from a boiler using anthracite coal :

$\text{CO}_2$ , 13.10 ; CO, 0.30 ; O, 11.94 ; N, 74.66.

The loss of heat due to burning C to CO instead of to  $\text{CO}_2$  was 2.13%. The surplus oxygen averaged 113.3% of the O required for the C of the fuel, the average for different weeks ranging from 88.6% to 137%.

Analyses made to determine the CO produced by excessively rapid firing gave results from 2.51% to 4.81% CO and 5.12 to 8.01%  $\text{CO}_2$ ; the ratio of C in the CO to total carbon burned being from 43.80% to 48.55%, and the number of pounds of air supplied to the furnace per pound of coal being from 33.2 to 19.3 lbs. The loss due to burning C to CO was from 27.84% to 30.86 of the full power of the coal.

**Temperature of the Fire.** (Rankine, S. E., p. 283.)—By temperature of the fire is meant the temperature of the products of combustion at the instant that the combustion is complete. The elevation of that temperature above the temperature at which the air and the fuel are supplied to the furnace may be computed by dividing the total heat of combustion of one lb. of fuel by the weight and by the mean specific heat of the whole products of combustion, and of the air employed for their dilution under constant pressure. The specific heat under constant pressure of these products is about as follows:

Carbonic-acid gas, 0.217; steam, 0.475; nitrogen (probably), 0.245; air, 0.238; ashes, probably about 0.200. Using these data, the following results are obtained for pure carbon and for olefiant gas burned, respectively, first, in just sufficient air, theoretically, for their combustion, and, second, when an equal amount of air is supplied in addition for dilution.

Fuel.	Products undiluted.		Products diluted.	
	Carbon.	Olefiant Gas.	Carbon.	Olefiant Gas.
Total heat of combustion, per lb...	14,500	21,300	14,500	21,300
Wt of products of combustion, lbs.	13	16.43	25	31.86
Their mean specific heat.....	0.237	0.257	0.238	0.248
Specific heat $\times$ weight.....	3.08	4.22	5.94	7.9
Elevation of temperature, F.....	4580°	5050°	2440°	2710°

[The above calculations are made on the assumption that the specific heats of the gases are constant, but they probably increase with the increase of temperature (see Specific Heat), in which case the temperature would be less than those above given. The temperature would be further

reduced by the heat rendered latent by the conversion into steam of any water present in the fuel.]

**Rise of Temperature in Combustion of Gases.** (*Eng'g*, March 12 and April 2, 1886.)—It is found that the temperatures obtained by experiment fall short of those obtained by calculation. Three theories have been given to account for this: 1. The cooling effect of the sides of the containing vessel; 2. The retardation of the evolution of heat caused by dissociation; 3. The increase of the specific heat of the gases at very high temperatures. The calculated temperatures are obtainable only on the condition that the gases shall combine instantaneously and simultaneously throughout their whole mass. This condition is practically impossible in experiments. The gases formed at the beginning of an explosion dilute the remaining combustible gases and tend to retard or check the combustion of the remainder.

**CLASSIFICATION OF SOLID FUELS.**

Gruner classifies solid fuels as follows (*Eng'g and M'g Jour.*, July, 1874):

Name of Fuel.	Ratio $\frac{O}{H}$ or $\frac{O+N*}{H}$ .	Proportion of Coke or Charcoal yielded by the Dry Pure Fuel.
Pure cellulose.....	8	0.28 @ 0.30
Wood (cellulose and encasing matter)....	7	.30 @ .35
Peat and fossil fuel ....	6 @ 5	.35 @ .40
Lignite,† or brown coal.....	5	.40 @ .50
Bituminous coals .....	4 @ 1	.50 @ .90
Anthracite.....	1 @ 0.75	.90 @ .92

The bituminous coals he divides into five classes as below:

Name of Type.	Elementary Composition.			Ratio $\frac{O}{H}$ or $\frac{O+N*}{H}$ .	Proportion of Coke yielded by Distillation.	Nature and Appearance of Coke.
	C.	H.	O.			
1. Long flaming dry coal,	75@80	5.5@4.5	19.5@15	4@3	0.50@.60	Pulverulent.
2. Long flaming fat or coking coals, or gas coals,						
3. Caking fat coals, or blacksmiths' coals,	84@89	5 @4.5	11 @5.5	2@1	.68@.74	Melted; somewhat compact.
4. Short flaming fat or caking coals, coking coals,						
5. Lean or anthracitic coals,	90@93	4.5@4	5.5@3	1	.82@.90	Pulverulent.

\* The nitrogen rarely exceeds 1 per cent of the weight of the fuel.

† Not including bituminous lignites, which resemble petroleum.

Rankine gives the following: The extreme differences in the chemical composition and properties of different kinds of coal are very great. The proportion of free carbon ranges from 30 to 93 per cent; that of hydrocarbons of various kinds from 5 to 58 per cent; that of water, or oxygen and hydrogen in the proportions which form water, from an inappreciably small quantity to 27 per cent; that of ash, from 1½ to 26 per cent.

The numerous varieties of coal may be divided into principal classes as follows: 1, anthracite coal; 2, semi-bituminous coal; 3, bituminous coal; 4, long flaming or cannel coal; 5, lignite or brown coal.

**Diminution of H and O in Series from Wood to Anthracite**

(Groves and Thorp's Chemical Technology, vol. i., Fuels, p. 58.)

Substance.	Carbon.	Hydrogen.	Oxygen.
Woody fibre. ....	52.65	5.25	42.10
Peat from Vulcaire .....	59.57	5.96	34.47
Lignite from Cologne.....	66.04	5.27	28.69
Earthy brown coal .....	73.18	5.88	21.14
Coal from Belestat, secondary.....	75.06	5.84	19.10
Coal from Rive de Gier.....	89.29	5.05	5.66
Anthracite, Mayenne, transition formation	91.58	3.96	4.46

**Progressive Change from Wood to Graphite.**

(J. S. Newberry in Johnson's Cyclopaedia.)

	Wood.	Loss.	Lig- nite.	Loss.	Bitumi- nous coal.	Loss.	Anthra- cite.	Loss.	Graph- ite.
Carbon.....	49.1	18.65	30.45	12.35	18.10	3.57	14.53	1.42	13.11
Hydrogen...	6.3	3.25	3.05	1.85	1.20	0.93	0.27	0.14	0.13
Oxygen.....	44.6	24.40	20.20	18.13	2.07	1.32	0.65	0.65	0.00
	100.0	46.30	53.70	32.33	21.37	5.82	15.45	2.21	13.24

**Classification of Coals, as Anthracite, Bituminous, etc.—**

Prof. Persifer Frazer (Trans. A. I. M. E., vi, 430) proposes a classification of coals according to their "fuel ratio," that is, the ratio the fixed carbon bears to the volatile hydrocarbon.

In arranging coals under this classification, the accidental impurities, such as sulphur, earthy matter, and moisture, are disregarded, and the fuel constituents alone are considered.

	Carbon Ratio.	Fixed Carbon.	Volatile Hydrocarbon.
I. Hard dry anthracite.	100 to 12	100. to 92.31%	0. to 7.69%
II. Semi-anthracite.....	12 to 8	92.31 to 88.89	7.69 to 11.11
III. Semi-bituminous. ...	8 to 5	88.89 to 83.33	11.11 to 16.67
IV. Bituminous. ....	5 to 0	83.33 to 0.	16.67 to 100

It appears to the author that the above classification does not draw the line at the proper point between the semi-bituminous and the bituminous coals, viz., at a ratio of C ÷ V.H.C. = 5, or fixed carbon 83.33%, volatile hydrocarbon 16.67%, since it would throw many of the steam coals of Clearfield and Somerset counties, Penn., and the Cumberland, Md., and Pocahontas, Va., coals, which are practically of one class, and properly rated as semi-bituminous coals, into the bituminous class. The dividing line between the semi-anthracite and semi-bituminous coals, C + V.H.C. = 8, would place several coals known as semi-anthracite in the semi-bituminous class. The following is proposed by the author as a better classification :

	Carbon Ratio.	Fixed Carbon.	Vol. H.C.
I. Hard dry anthracite..	100 to 12	100 to 92.31%	0 to 7.69%
II. Semi-anthracite.....	12 to 7	92.31 to 87.5	7.69 to 12.5
III. Semi-bituminous.....	7 to 3	87.5 to 75	12.5 to 25
IV. Bituminous .....	3 to 0	75 to 0	25 to 100

**Rhode Island Graphitic Anthracite.**—A peculiar graphite is found at Cranston, near Providence, R. I. It resembles both graphite and anthracite coal, and has about the following composition (A. E. Hunt, Trans. A. I. M. E., xvii., 678): Graphitic carbon, 78%; volatile matter, 2.60%; silica, 15.06%; phosphorus, .045%. It burns with extreme difficulty.

**ANALYSES OF COALS.**

**Composition of Pennsylvania Anthracites.** (Trans. A. I. M. E., xiv., 706.)—Samples weighing 100 to 200 lbs. were collected from lots of 100 to 200 tons as shipped to market, and reduced by proper methods to laboratory samples. Thirty-three samples were analyzed by McCreath, giving results as follows. They show the mean character of the coal of the more important coal-beds in the Northern field in the vicinity of Wilkesbarre, in the Eastern Middle (Lehigh) field in the vicinity of Hazleton, in the Western

Middle field in the vicinity of Shenandoah, and in the Southern field between Mauch Chunk and Tamaqua.

Name of Bed.	Name of Field.	Water.	Volatile Matter.	Fixed Carbon.	Ash.	Sulphur.	Vol. Matter: Per cent of total combustible.	Ratio, C + V.H.C.
Wharton...	E. Middle	3.71	3.08	86.40	6.22	.58	3.44	28.07
Mammoth..	E. Middle	4.12	3.08	86.38	5.92	.49	3.45	27.99
Primrose ..	W. Middle	3.54	3.72	81.59	10.65	.50	4.36	21.93
Mammoth..	W. Middle	3.16	3.72	81.14	11.08	.90	4.38	21.83
Primrose F	Southern	3.01	4.13	87.98	4.38	.50	4.48	21.32
Buck Mtn..	W. Middle	3.04	3.95	82.66	9.88	.46	4.56	20.93
Seven Foot	W. Middle	3.41	3.98	80.87	11.23	.51	4.69	20.32
Mammoth..	Southern	3.09	4.28	83.81	8.18	.64	4.85	19.62
Mammoth..	Northern	3.42	4.38	83.27	8.20	.73	5.00	19.00
B. Coal Bed	Loyalsock	1.30	8.10	83.34	6.23	1.03	8.86	10.29

The above analyses were made of coals of all sizes (mixed). When coal is screened into sizes for shipment the purity of the different sizes as regards ash varies greatly. Samples from one mine gave results as follows:

Name of Coal.	Screened		Fixed Carbon.	Ash.
	Through inches.	Over inches.		
Egg .....	2.5	1.75	88.49	5.66
Stove .....	1.75	1.25	83.67	10.17
Chestnut.....	1.25	.75	80.72	12.67
Pea.....	.75	.50	79.05	14.66
Buckwheat...	.50	.25	76.92	16.62

### Bernice Basin, Pa., Coals.

	Water.	Vol. H.C.	Fixed C.	Ash.	Sulphur.
Bernice Basin, Sullivan and Lycoming Cos.; range of 8..	0.96 to 1.97	3.56 to 8.56	82.52 to 89.39	3.27 to 9.34	0.24 to 1.04

This coal is on the dividing-line between the anthracites and semi-anthracites, and is similar to the coal of the Lykens Valley district.

More recent analyses (Trans. A. I. M. E., xiv. 721) give:

	Water.	Vol. H.C.	Fixed Carb.	Ash.	Sulphur.
Working seam.....	0.65	9.40	83.69	5.34	0.91
60 ft. below seam....	3.67	15.42	71.34	8.97	0.59

The first is a semi-anthracite, the second a semi-bituminous.

**Space Occupied by Anthracite Coal.** (J. C. I. W., vol. iii.)—The cubic contents of 2240 lbs. of hard Lehigh coal is a little over 36 feet; an average Schuylkill W. A., 37 to 38 feet; Shamokin, 38 to 39 feet; Lorberrry, nearly 41.

According to measurements made with Wilkesbarre anthracite coal from the Wyoming Valley, it requires 32.2 cu. ft. of lump, 33.9 cu. ft. broken, 34.5 cu. ft. egg, 34.8 cu. ft. of stove, 35.7 cu. ft. of chestnut, and 36.7 cu. ft. of pea, to make one ton of coal of 2240 lbs.; while it requires 28.8 cu. ft. of lump, 30.3 cu. ft. of broken, 30.8 cu. ft. of egg, 31.1 cu. ft. of stove, 31.9 cu. ft. of chestnut, and 32.8 cu. ft. of pea, to make one ton of 2000 lbs.

**Composition of Anthracite and Semi-bituminous Coals.** (Trans. A. I. M. E., vi. 430.)—Hard dry anthracites, 16 analyses by Rogers, show a range from 94.10 to 82.47 fixed carbon, 1.40 to 9.53 volatile matter, and 4.50 to 8.00 ash, water, and impurities. Of the fuel constituents alone, the fixed carbon ranges from 93.53 to 89.63, and the volatile matter from 1.47 to 10.37, the corresponding carbon ratios, or C ÷ Vol. H.C. being from 67.02 to 8.64.

*Semi-anthracites.*—12 analyses by Rogers show a range of from 90.23 to 74.55 fixed carbon, 7.07 to 13.75 volatile matter, and 2.20 to 12.10 water, ash, and impurities. Excluding the ash, etc., the range of fixed carbon is 92.75 to 84.42, and the volatile combustible 7.27 to 15.58, the corresponding carbon ratio being from 12.75 to 5.41.

*Semi-bituminous Coals.*—10 analyses of Penna. and Maryland coals give fixed carbon 68.41 to 84.80, volatile matter 11.2 to 17.28, and ash, water, and impurities 4 to 13.99. The percentage of the fuel constituents is fixed carbon 79.84 to 88.80, volatile combustible 11.20 to 20.16, and the carbon ratio 11.41 to 3.96.

### American Semi-bituminous and Bituminous Coals.

(Selected chiefly from various papers in Trans. A. I. M. E.)

The percentage of volatile matter in the Kittaning lower bed B and the Freeport lower bed D increases with great uniformity from east to west; thus:

	Volatile Matter.	Fixed Carbon.
Clearfield Co, bed D.....	20.09 to 25.19	68.73 to 74.76
“ “ “ B.....	22.56 to 26.13	64.37 to 69.63
Clarion Co., “ B.....	35.70 to 42.55	47.51 to 55.44
“ “ “ D.....	37.15 to 40.80	51.39 to 56.36

### Connellsville Coal and Coke. (Trans. A. I. M. E., xiii. 332.)—

The Connellsville coal-field, in the southwestern part of Pennsylvania, is a strip about 3 miles wide and 60 miles in length. The mine workings are confined to the Pittsburgh seam, which here has its best development as to size, and its quality best adapted to coke-making. It generally affords from 7 to 8 feet of coal.

The following analyses by T. T. Morrell show about its range of composition :

	Moisture.	Vol. Mat.	Fixed C.	Ash.	Sulphur.	Phosph's.
Herold Mine ....	1.26	28.83	60.79	8.44	.67	.013
Kintz Mine.....	0.79	31.91	56.46	9.52	1.32	.02

In comparing the composition of coals across the Appalachian field, in the western section of Pennsylvania, it will be noted that the Connellsville variety occupies a peculiar position between the rather dry semi-bituminous coals eastward of it and the fat bituminous coals flanking it on the west.

Beneath the Connellsville or Pittsburgh coal-bed occurs an interval of from 400 to 600 feet of "barren measures," separating it from the lower productive coal measures of Western Pennsylvania. The following tables

show the great similarity in composition in the coals of these upper and lower coal-measures in the same geographical belt or basin.

**Analyses from the Upper Coal-measures (Penna.) in a Westward Order.**

\* *Indiana Block Coal* (J. S. Alexander, Trans. A. I. M. E., iv. 100).—The typical block coal of the Brazil (Indiana) district differs in chemical composition but little from the coking coals of Western Pennsylvania. The physical difference, however, is quite marked; the latter has a cuboid structure made up of bituminous particles lying against each other, so that under the action of heat fusion throughout the mass readily takes place, while block coal is formed of alternate layers of rich bituminous matter and a charcoal-like substance, which is not only very slow of combustion, but so retards the transmission of heat that agglutination is prevented, and the coal burns away layer by layer, retaining its form until consumed.

An ultimate analysis of block coal from Sand Creek by E. T. Cox gave: C, 72.94; H, 4.50; O, 11.77; N, 1.79; ash, 4.50; moisture, 4.50.

† The Illinois coals are generally high in moisture, volatile matter, sulphur and ash, and are consequently low in heating value. The range of quality is a wide one. The Big Muddy coal of Jackson Co., which has a high reputation as a steam coal, has, according to the analysis given above, about 36% of volatile matter in the total combustible, corresponding to the coals of Western Pennsylvania and Ohio, while the Staunton coal has 68%, ranking it among the poorer varieties of lignite. A boiler-test with this coal (see p. 636, also Trans. A. S. M. E., v. 266) gave only 6.19 lbs. water evaporated from and at 212° per lb. combustible. The Staunton coal is remarkable for the high percentage of volatile matter, but it is excelled in this respect by

the Boghead coal of Linlithgowshire, Scotland, an analysis of which by Dr. Penny is as follows: Proximate—moisture 0.84; vol. 67.95; fixed C, 9.54, ash, 21.4; Ultimate—C, 63.94; H, 8.86; O, 4.70; N, 0.96; which is remarkable for the high percentage of H.

\* The analyses of Iowa, Missouri, Nebraska, and Wyoming coals are selected from a paper on The Heating Value of Western Coals, by Win. Forsyth, Mech. Engr. of the C., B. & Q. R. R., *Eng'g News*, Jan. 17, 1895.

† Includes sulphur, which is very high. Coke from Cedar City analyzed: Water and volatile matter, 1.42; fixed carbon, 76.70; ash, 16.61; sulphur, 5.27.

‡ *Colorado Coals.*—The Colorado coals are of extremely variable composition, ranging all the way from lignite to anthracite. G. C. Hewitt (Trans. A. I. M. E., xvii. 377) says: The coal seams, where unchanged by heat and flexure, carry a lignite containing from 5% to 20% of water. In the south-eastern corner of the field the same have been metamorphosed so that in four miles the same seams are an anthracite, coking, and dry coal. In the basin of Coal Creek the coals are extremely fat, and produce a hard, bright, sonorous coke. North of coal basin half a mile of development shows a gradual change from a good coking coal with patches of dry coal to a dry coal that will barely agglutinate in a beehive oven. In another half mile the same seam is dry. In this transition area, a small cross-fault makes the coal fat for twenty or more feet on either side. The dry seams also present wide chemical and physical changes in short distances. A soft and loosely bedded coal has in a hundred feet become compact and hard without the intervention of a fault. A couple of hundred feet has reduced the water of combination from 12% to 5%.

**Western Arkansas and Indian Territory.** (H. M. Chance, Trans. A. I. M. E. 1890.)—The Choctaw coal-field is a direct westward exten-

sion of the Arkansas coal-field, but its coals are not like Arkansas coals, except in the country immediately adjoining the Arkansas line.

The western Arkansas coals are dry semi-bituminous or semi-anthracitic coals, mostly non-coking, or with quite feeble coking properties, ranging from 14% to 16% in volatile matter, the highest percentage yet found, according to Mr. Winslow's Arkansas report, being 17.655.

In the Mitchell basin, about 10 miles west from the Arkansas line, coal recently opened shows 19% volatile matter; the Mayberry coal, about 8 miles farther west, contains 23% volatile matter; and the Bryan Mine coal, about the same distance west, shows 26% volatile matter. About 30 miles farther west, the coal shows from 38% to 41½% volatile matter, which is also about the percentage in coals of the McAlester and Lehigh districts.

**Western Lignites.** (R. W. Raymond, Trans. A. I. M. E., vol. ii. 1873.)

The calorific power is calculated by Dulong's formula,

$$8080C + 34462\left(H - \frac{O}{8}\right),$$

deducting the heat required to vaporize the moisture and combined water, that is, 537 calories for each unit of water. 1 calorie = 1.8 British thermal units.

An analysis of Pictou, N. S., coal, in Trans. A. I. M. E., xiv. 560, is: Vol., 29.63; carbon, 56.98; ash, 13.39; and one of Sydney, Cape Breton, coal is: vol., 34.07; carbon, 61.43; ash, 4.50.

**Nixon's Navigation Welsh Coal** is remarkably pure, and contains not more than 3 to 4 per cent of ashes, giving 88 per cent of hard and lustrous coke. The quantity of fixed carbon it contains would classify it among the dry coals, but on account of its coke and its intensity of combustion it belongs to the class of fat, or long-flaming coals.

Chemical analysis gave the following results: Carbon, 90.27; hydrogen, 4.39; sulphur, .69; nitrogen, .49; oxygen (difference), 4.16.

The analysis showed the following composition of the volatile parts: Carbon, 22.53; hydrogen, 34.96; O + N + S, 42.51.

The heat of combustion was found to be, as a result of several experiments, 8864 calories for the unit of weight. Calculated according to its composition, the heat of combustion would be 8805 calories = 15,849 British thermal units per pound.

This coal is generally used in trial-trips of steam-vessels in Great Britain.

**Sampling Coal for Analysis.**—J. P. Kimball, Trans. A. I. M. E., xii. 317, says: The unsuitable sampling of a coal-seam, or the improper preparation of the sample in the laboratory, often gives rise to errors in determinations of the ash so wide in range as to vitiate the analysis for all practical purposes; every other single determination, excepting moisture, showing its relative part of the error. The determination of sulphur and ash are especially liable to error, as they are intimately associated in the slates.

Wm. Forsyth, in his paper on *The Heating Value of Western Coals* (*Eng'g News*, Jan. 17, 1895), says: This trouble in getting a fairly average sample of anthracite coal has compelled the Reading R. R. Co., in getting their samples, to take as much as 300 lbs. for one sample, drawn direct from the chutes, as it stands ready for shipment.

The directions for collecting samples of coal for analysis at the C., B. & Q. laboratory are as follows:

Two samples should be taken, one marked "average," the other "select." Each sample should contain about 10 lbs., made up of lumps about the size of an orange taken from different parts of the dump or car, and so selected that they shall represent as nearly as possible, first, the average lot; second, the best coal.

An example of the difference between an "average" and a "select" sample, taken from Mr. Forsyth's paper, is the following of an Illinois coal:

	Moisture.	Vol. Mat.	Fixed Carbon.	Ash.
Average .....	1.36	27.69	35.41	35.54
Select.....	1.90	31.70	48.23	15.17

The theoretical evaporative power of the former was 9.13 lbs. of water from and at 212° per lb. of coal, and that of the latter 11.44 lbs.

**Relative Value of Fine Sizes of Anthracite.**—For burning on a grate coal-dust is commercially valueless, the finest commercial anthracites being sold at the following rates per ton at the mines, according to an address by Mr. Eckley B. Coxé (1893):

Size.	Range of Size.	Price at Mines.
Chestnut.....	1½ to ¾ inch	\$2.75
Pea.....	¾ to 9/16	1.25
Buckwheat.....	9/16 to ¾	0.75
Rice.....	¾ to 3/16	0.25
Barley.....	3/16 to 2/32	0.10

But when coal is reduced to an impalpable dust, a method of burning it becomes possible to which even the finest of these sizes is wholly unadapted; the coal may be blown in as dust, mixed with its proper proportion of air, and no grate at all is then required.

**Pressed Fuel.** (E. F. Loiseau, Trans. A. I. M. E., viii. 314.)—Pressed fuel has been made from anthracite dust by mixing the dust with ten per cent of its bulk of dry pitch, which is prepared by separating from tar at a temperature of 572° F. the volatile matter it contains. The mixture is kept heated by steam to 212°, at which temperature the pitch acquires its cementing properties, and is passed between two rollers, on the periphery of which are milled out a series of semi-oval cavities. The lumps of the mixture, about the size of an egg, drop out under the rollers on an endless belt which carries them to a screen in eight minutes, which time is sufficient to cool the lumps, and they are then ready for delivery.

The enterprise of making the pressed fuel above described was not commercially successful, on account of the low price of other coal. In France, however, "briquettes" are regularly made of coal-dust (bituminous and semi-bituminous),

**RELATIVE VALUE OF STEAM COALS.**

The heating value of a coal may be determined, with more or less approximation to accuracy, by three different methods.

1st, by chemical analysis; 2d, by combustion in a coal calorimeter; 3d, by actual trial in a steam-boiler. The first two methods give what may be called the theoretical heating value, the third gives the practical value.

The accuracy of the first two methods depends on the precision of the method of analysis or calorimetry adopted, and upon the care and skill of the operator. The results of the third method are subject to numerous sources of variation and error, and may be taken as approximately true only for the particular conditions under which the test is made. Analysis and calorimetry give with considerable accuracy the heating value which may be obtained under the conditions of perfect combustion and complete absorption of the heat produced. A boiler test gives the actual result under conditions of more or less imperfect combustion, and of numerous and variable wastes. It may give the highest practical heating value, if the conditions of grate-bars, draft, extent of heating surface, method of firing, etc., are the best possible for the particular coal tested, and it may give results far beneath the highest if these conditions are adverse or unsuitable to the coal.

The results of boiler tests being so extremely variable, their use for the purpose of determining the relative steaming values of different coals has frequently led to false conclusions. A notable instance is found in the record of Prof. Johnson's tests, made in 1844, the only extensive series of tests of American coals ever made. He reported the steaming value of the Lehigh Coal & Navigation Co.'s coal to be far the lowest of all the anthracites, a result which is easily explained by an examination of the conditions under which he made the test, which were entirely unsuited to that coal. He also reported a result for Pittsburgh coal which is far beneath that now obtainable in every-day practice, his low result being chiefly due to the use of an improper furnace.

In a paper entitled Proposed Apparatus for Determining the Heating Power of Different Coals (Trans. A. I. M. E., xiv. 727) the author described and illustrated an apparatus designed to test fuel on a large scale, avoiding the errors of a steam-boiler test. It consists of a fire-brick furnace enclosed in a water-casing, and two cylindrical shells containing a great number of tubes, which are surrounded by cooling water and through which the gases of combustion pass while being cooled. No steam is generated in the apparatus, but water is passed through it and allowed to escape at a temperature below 200° F. The product of the weight of the water passed through the apparatus by its increase in temperature is the measure of the heating value of the fuel.

There has been much difference of opinion concerning the value of chemical analysis as a means of approximating the heating power of coal. It was found by Scheurer-Kestner and Meunier-Dollfus, in their extensive series of tests, made in Europe in 1868, that the heating power as determined by calorimetric tests was greater than that given to chemical analysis according to Dulong's law.

Recent tests made in Paris by M. Mahler, however, show a much closer agreement of analysis and calorimetric tests. A brief description of these tests, translated from the French, may be found in an article by the author in *The Mineral Industry*, vol. i. page 97.

Dulong's law may be expressed by the formula,

$$\text{Heating Power in British Thermal Units} = 14,500C + 62,500 \left( H - \frac{O}{8} \right),*$$

in which C, H, and O are respectively the percentage of carbon, hydrogen, and oxygen, each divided by 100. A study of M. Mahler's calorimetric tests shows that the maximum difference between the results of these tests and the calculated heating power by Dulong's law in any single case is only a little over 3%, and the results of 31 tests show that Dulong's formula gives an average of only 47 thermal units less than the calorimetric tests, the average total heating value being over 14,000 thermal units, a difference of less than 4/10 of 1%.

\* Mahler gives Dulong's formula with Berthelot's figure for the heating value of carbon, in British thermal units,

$$\text{Heating Power} = 14,650C + 62,025 \left( H - \frac{(O + N) - 1}{8} \right).$$

Mahler's calorimetric apparatus consists of a strong steel vessel or "bomb" immersed in water, proper precaution being taken to prevent radiation. One gram of the coal to be tested is placed in a platinum boat within this bomb, oxygen gas is introduced under a pressure of 20 to 25 atmospheres, and the coal ignited explosively by an electric spark. Combustion is complete and instantaneous, the heat is radiated into the surrounding water, weighing 2200 grams, and its quantity is determined by the rise in temperature of this water, due corrections being made for the heat capacity of the apparatus itself. The accuracy of the apparatus is remarkable, duplicate tests giving results varying only about 2 parts in 1000.

The close agreement of the results of calorimetric tests when properly conducted, and of the heating power calculated from chemical analysis, indicates that either the chemical or the calorimetric method may be accepted as correct enough for all practical purposes for determining the total heating power of coal. The results obtained by either test method may be taken as a standard by which the results of a boiler test are to be compared, and the difference between the total heating power, and the result of the boiler test is a measure of the inefficiency of the boiler under the conditions of any particular test.

In practice with good anthracite coal, in a steam-boiler properly proportioned, and with all conditions favorable, it is possible to obtain in the steam 80% of the total heat of combustion of the coal. This result was nearly obtained in the tests at the Centennial Exhibition in 1876, in five different boilers. An efficiency of 70% to 75% may easily be obtained in regular practice. With bituminous coals it is difficult to obtain as close an approach to the theoretical maximum of economy, for the reason that some of the volatile combustible portion of the coal escapes unburned, the difficulty increasing rapidly as the content of volatile matter increases beyond 20%. With most coals of the Western States it is with difficulty that as much as 60% or 65% of the theoretical efficiency can be obtained without the use of gas-producers.

The chemical analysis heretofore referred to is the ultimate analysis, or the percentage of carbon, hydrogen, and oxygen of the dry coal. It is found, however, from a study of Mahler's tests that the proximate analysis, which gives fixed carbon, volatile matter, moisture, and ash, may be relied on as giving a measure of the heating value with a limit of error of only about 3%. After deducting the moisture and ash, and calculating the fixed carbon as a percentage of the coal dry and free from ash, the author has constructed the following table:

APPROXIMATE HEATING VALUE OF COALS.

Percentage F. C. in Coal Dry and Free from Ash.	Heating Value B.T.U. per lb. Comb'l.e.	Equiv. Water Evap. from and at 212° per lb. Combustible.	Percentage F. C. in Coal Dry and Free from Ash.	Heating Value B.T.U. per lb. Comb'l.e.	Equiv. Water Evap. from and at 212° per lb. Combustible.

87	15660	16.21	54	13320	13.79
80	15840	16.40	51	12600	13.04
72	15660	16.21	50	12240	12.67

Below 50% the law of decrease of heating-power shown in the table apparently does not hold, as some cannel coals and lignites show much higher heating-power than would be predicted from their chemical constitution.

The use of this table may be shown as follows:

Given a coal containing moisture 2%, ash 8%, fixed carbon 61%, and volatile matter 29%, what is its probable heating value? Deducting moisture and ash we find the fixed carbon is 61/90 or 68% of the total of fixed carbon and volatile matter. One pound of the coal dry and free from ash would, by the table, have a heating value of 15,480 thermal units, but as the ash and moisture, having no heating value, are 10% of the total weight of the coal, the coal would have 90% of the table value, or 13,932 thermal units. This divided by 966, the latent heat of steam at 212° gives an equivalent evaporation per lb. of coal of 14.42 lbs.

The heating value that can be obtained in practice from this coal would depend upon the efficiency of the boiler, and this largely upon the difficulty of thoroughly burning its volatile combustible matter in the boiler furnace. If a boiler efficiency of 65% could be obtained, then the evaporation per lb. of coal from and at 212° would be  $14.42 \times .65 = 9.37$  lbs.

With the best anthracite coal, in which the combustible portion is, say, 97% fixed carbon and 3% volatile matter, the highest result that can be expected in a boiler-test with all conditions favorable is 12.2 lbs. of water evaporated from and at 212° per lb. of combustible, which is 80% of 15.28 lbs. the theoretical heating-power. With the best semi-bituminous coals, such as Cumberland and Pocahontas, in which the fixed carbon is 80% of the total combustible, 12.5 lbs., or 76% of the theoretical 16.4 lbs., may be obtained. For Pittsburgh coal, with a fixed carbon ratio of 68%, 11 lbs., or 69% of the theoretical 16.03 lbs., is about the best practically obtainable with the best boilers. With some good Ohio coals, with a fixed carbon ratio of 60%, 10 lbs., or 66% of the theoretical 15.09 lbs., has been obtained, under favorable conditions, with a fire-brick arch over the furnace. With coals mined west of Ohio, with lower carbon ratios, the boiler efficiency is not apt to be as high as 60%.

From these figures a table of probable maximum boiler-test results from coals of different fixed carbon ratios may be constructed as follows:

Fixed carbon ratio.....	97	80	68	60	54	50
Evap. from and at 212° per lb. combustible, maximum in boiler-tests:	12.2	12.5	11	10	8.3	7.0
Boiler efficiency, per cent.....	80	76	69	66	60	55
Loss, chimney, radiation, imperfect combustion, etc :	20	24	31	34	40	45

The difference between the loss of 20% with anthracite and the greater losses with the other coals is chiefly due to imperfect combustion of the bituminous coals, the more highly volatile coals sending up the chimney the greater quantity of smoke and unburned hydrocarbon gases. It is a measure of the inefficiency of the boiler furnace and of the inefficiency of heating-surface caused by the deposition of soot, the latter being primarily caused by the imperfection of the ordinary furnace and its unsuitability to the proper burning of bituminous coal. If in a boiler-test with an ordinary furnace lower results are obtained than those in the above table, it is an indication of unfavorable conditions, such as bad firing, wrong proportions of boiler, defective draft, and the like, which are remediable. Higher results can be expected only with gas-producers, or other styles of furnace especially designed for smokeless combustion.

**Kind of Furnace Adapted for Different Coals.** (From the author's paper on "The Evaporative Power of Bituminous Coals," Trans. A. S. M. E., iv, 257.)—Almost any kind of a furnace will be found well adapted to burning anthracite coals and semi-bituminous coals containing less than 20% of volatile matter. Probably the best furnace for burning those coals which contain between 20% and 40% volatile matter, including the Scotch, English, Welsh, Nova Scotia, and the Pittsburgh and Monongahela river coals, is a plain grate-bar furnace with a fire-brick arch thrown over it, for the purpose of keeping the combustion-chamber thoroughly hot. The best furnace for coals containing over 40% volatile matter will be a furnace surrounded by fire-brick with a large combustion-chamber, and some special appliance for introducing very hot air to the gases distilled from the coal, or, preferably, a separate gas-producer and combustion-chamber, with facilities for heating both air and gas before they unite in the combustion-chamber. The character of furnace to be especially avoided in burning all bituminous coals containing over 20% of volatile matter is the ordinary furnace, in which the boiler is set directly above the grate bars, and in which the heating-surfaces of the boiler are directly exposed to radiation from the coal on the grate. The question of admitting air above the grate is still unsettled. The London *Engineer* recently said: "All our experience, extending over many years, goes to show that when the production of smoke is prevented by special devices for admitting air, either there is an increase in the consumption of fuel or a diminution in the production of steam. \* \* \* The best smoke-preventer yet devised is a good fireman."

**Downward-draught Furnaces.**—Recent experiments show that with bituminous coal considerable saving may be made by causing the draught to go downwards from the freshly-fired coal through the hot coal on the grate. Similar good results are also obtained by the upward draught by feeding the fresh coal under the bed of hot coal instead of on top. (See Boilers.)

**Calorimetric Tests of American Coals.**—From a number of tests of American and foreign coals, made with an oxygen calorimeter, by Geo. H. Barrus (Trans. A. S. M. E., vol. xiv. 816), the following are selected, showing the range of variation:

	Percentage of Ash.	Total Heat of Combustion. B. T. U.	Total Heat reduced to Fuel free from Ash.
<i>Semi-bituminous.</i>

Place of Test: 1. London, England; 2. Peacedale, R. I.; 3. Cincinnati, O.; 4. Pittsburgh, Pa.; 5. Chicago, Ill.; 6. Springfield, O.; 7. San Francisco, Cal.

In all the above tests the furnace was supplied with a fire-brick arch for preventing the radiation of heat from the coal directly to the boiler.

**Weathering of Coal.** (I. P. Kimball, Trans. A. I. M. E., viii. 204.)—The practical effect of the weathering of coal, while sometimes increasing its absolute weight, is to diminish the quantity of carbon and disposable hydrogen and to increase the quantity of oxygen and of indisposable hydrogen. Hence a reduction in the calorific value.

An excess of pyrites in coal tends to produce rapid oxidation and mechanical disintegration of the mass, with development of heat, loss of coking power, and spontaneous ignition.

The only appreciable results of the weathering of anthracite within the ordinary limits of exposure of stocked coal are confined to the oxidation of its accessory pyrites. In coking coals, however, weathering reduces and finally destroys the coking power, while the pyrites are converted from the state of bisulphide into comparatively innocuous sulphates.

Richters found that at a temperature of 158° to 180° Fahr., three coals lost in fourteen days an average of 3.6% of calorific power. (See also paper by R. P. Rothwell, Trans. A. I. M. E., iv. 55.)

**COKE.**

Coke is the solid material left after evaporating the volatile ingredients of coal, either by means of partial combustion in furnaces called coke ovens, or by distillation in the retorts of gas-works.

Coke made in ovens is preferred to gas coke as fuel. It is of a dark-gray color, with slightly metallic lustre, porous, brittle, and hard.

The proportion of coke yielded by a given weight of coal is very different for different kinds of coal, ranging from 0.9 to 0.35.

Being of a porous texture, it readily attracts and retains water from the atmosphere, and sometimes, if it is kept without proper shelter, from 0.15 to 0.20 of its gross weight consists of moisture.

**Analyses of Coke.**

(From report of John R. Procter, Kentucky Geological Survey.)

Where Made.	Fixed Carbon	Ash.	Sulphur.
Connellsville, Pa. (Average of 3 samples).....	88.96	9.74	0.810

**Experiments in Coking. CONNELLSVILLE REGION.**

(John Fulton, Amer. Mfr., Feb. 10, 1893.)

No. of Test.	Time in Oven.	Coal Charged.	Ash made.	Fine Coke made.	Market Coke made	Total Coke made.	Per cent of Yield.				Per Cent Lost.
							Ash.	Fine Coke.	Market Coke	Total Coke.	
1	h. m. 67 00	lb. 12,420	lb. 99	lb. 385	lb. 7,518	lb. 7,903	00.80	3 10	60.53	63.63	35.57
2	68 00	11,090	90	359	6,580	6,939	00.81	3.24	59.33	62.57	36.62
3	45 00	9,120	77	272	5,418	5,690	00.84	2.98	59.41	62.39	36.77
4	45 00	9,020	74	349	5,334	5,683	00.82	3 87	59.13	63.00	36.18
		41,650	340	1365	24,850	26,215	00.82	3.28	59.66	62.94	36.24

These results show, in a general average, that Connellsville coal carefully coked in a modern beehive oven will yield 66.17% of marketable coke, 2.30% of small coke or braize, and 0.82% of ash.

The total average loss in volatile matter expelled from the coal in coking amounts to 30.71%.

The modern beehive coke oven is 12 feet in diameter and 7 feet high at crown of dome. It is used in making 48 and 72 hour coke.

In making these tests the coal was weighed as it was charged into the oven; the resultant marketable coke, small coke or braize and ashes weighed dry as they were drawn from the oven.

**Coal Washing.**—In making coke from coals that are high in ash and sulphur, it is advisable to crush and wash the coal before coking it. A coal-washing plant at Brookwood, Ala., has a capacity of 50 tons per hour. The average percentage of ash in the coal during ten days' run varied from 14% to 21%, in the washed coal from 4.8% to 8.1%, and in the coke from 6.1% to 10.5%. During three months the average reduction of ash was 60.9%. (*Eng. and Mining Jour.*, March 25, 1893.)

**Recovery of By-products in Coke Manufacture.**—In Germany considerable progress has been made in the recovery of by-products. The Hoffman-Otto oven has been most largely used, its principal feature being that it is connected with regenerators. In 1884 40 ovens on this system were running, and in 1892 the number had increased to 1209.

A Hoffman-Otto oven in Westphalia takes a charge of 6¼ tons of dry coal and converts it into coke in 48 hours. The product of an oven annually is 1025 tons in the Ruhr district, 1170 tons in Silesia, and 960 tons in the Saar district. The yield from dry coal is 75% to 77% of coke, 2.5% to 3% of tar, and 1.1% to 1.2% of sulphate of ammonia in the Ruhr district; 65% to 70% of coke, 4% to 4.5% of tar, and 1% to 1.25% of sulphate of ammonia in the Upper Silesia region and 68% to 72% of coke, 4% to 4.3% of tar and 1.8% to 1.9% of sulphate of ammonia in the Saar district. A group of 60 Hoffman ovens, therefore, yields annually the following:

District.	Coke, tons.	Tar, tons.	Sulphate Ammonia, tons.
Ruhr .....	51,200	1860	780
Upper Silesia.....	48,000	3000	840
Saar.....	40,500	2400	492

An oven which has been introduced lately into Germany in connection with the recovery of by-products is the Semet-Solvay, which works hotter than the Hoffman-Otto, and for this reason 73% to 77% of gas coal can be mixed with 23% to 27% of coal low in volatile matter, and yet yield a good coke. Mixtures of this kind yield a larger percentage of coke, but, on the other hand, the amount of gas is lessened, and therefore the yield of tar and ammonia is not so great.

The yield of coke by the beehive and the retort ovens respectively is given as follows in a pamphlet of the Solvay Process Co.: Connellsville coal: beehive, 66%, retort, 73%; Pocahontas: beehive, 62%, retort, 83%; Alabama: beehive, 60%, retort, 74%. (See article in *Mineral Industry*, vol. viii., 1900.)

References: F. W. Luerman, Verein Deutscher Eisenhuettenleute 1891, *Iron Age*, March 31, 1892; *Amer. Mfr.*, April 28, 1893. An excellent series of articles on the manufacture of coke, by John Fulton, of Johnstown, Pa., is published in the *Colliery Engineer*, beginning in January, 1893.

**Making Hard Coke.**—J. J. Fronheiser and C. S. Price, of the Cambria Iron Co., Johnstown, Pa., have made an improvement in coke manufacture by which coke of any degree of hardness may be turned out. It is accomplished by first grinding the coal to a coarse powder and mixing it with a hydrate of lime (air or water slacked caustic lime) before it is charged into the coke-ovens. The caustic lime or other fluxing material used is mechanically combined with the coke, filling up its cell-walls. It has been found that about 5% by weight of caustic lime mixed with the fine coal gives the best results. However, a larger quantity of lime can be added to coals containing more than 5% to 7% of ash. (*Amer. Mfr.*)

**Generation of Steam from the Waste Heat and Gases of Coke-ovens.** (Erskine Ramsey, *Amer. Mfr.*, Feb. 16, 1894.)—The gases from a number of adjoining ovens of the beehive type are led into a long horizontal flue, and thence to a combustion chamber under a battery of boilers. Two plants are in satisfactory operation at Tracy City, Tenn., and two at Pratt Mines, Ala.

**A Bushel of Coal.**—The weight of a bushel of coal in Indiana is 70 lbs., in Penna. 76 lbs.; in Ala., Colo., Ga., Ill., Ohio, Tenn., and W. Va. it is 80 lbs.

**A Bushel of Coke** is almost uniformly 40 lbs., but in exceptional

cases, when the coke is very light, 38, 36, and 33 lbs. are regarded as a bushel. In others, from 42 to 50 lbs. are given as the weight of a bushel; in this case the coke would be quite heavy.

**Products of the Distillation of Coal.**—S. P. Sadler's Handbook of Industrial Organic Chemistry gives a diagram showing over 50 chemical products that are derived from distillation of coal. The first derivatives are coal-gas, gas-liquor, coal-tar, and coke. From the gas-liquor are derived ammonia and sulphate, chloride and carbonate of ammonia. The coal-tar is split up into oils lighter than water or crude naphtha, oils heavier than water—otherwise dead oil or tar, commonly called creosote,—and pitch. From the two former are derived a variety of chemical products.

From the coal-tar there comes an almost endless chain of known combinations. The greatest industry based upon their use is the manufacture of dyes, and the enormous extent to which this has grown can be judged from the fact that there are over 600 different coal-tar colors in use, and many more which as yet are too expensive for this purpose. Many medicinal preparations come from the series, pitch for paving purposes, and chemicals for the photographer, the rubber manufacturers and tanners, as well as for preserving timber and cloths.

The composition of the hydrocarbons in a soft coal is uncertain and quite complex; but the ultimate analysis of the average coal shows that it approaches quite nearly to the composition of  $\text{CH}_4$  (marsh-gas). (W. H. Blauvelt, Trans. A. I. M. E., xx. 625.)

## WOOD AS FUEL.

Wood, when newly felled, contains a proportion of moisture which varies very much in different kinds and in different specimens, ranging between 30% and 50%, and being on an average about 40%. After 8 or 12 months' ordinary drying in the air the proportion of moisture is from 20 to 25%. This degree of dryness, or almost perfect dryness if required, can be produced by a few days' drying in an oven supplied with air at about 240° F. When coal or coke is used as the fuel for that oven, 1 lb. of fuel suffices to expel about 3 lbs. of moisture from the wood. This is the result of experiments on a large scale by Mr. J. R. Napier. If air-dried wood were used as fuel for the oven, from 2 to 2½ lbs. of wood would probably be required to produce the same effect.

The specific gravity of different kinds of wood ranges from 0.3 to 1.2.

Perfectly dry wood contains about 50% of carbon, the remainder consisting almost entirely of oxygen and hydrogen in the proportions which form water. The coniferous family contain a small quantity of turpentine, which is a hydrocarbon. The proportion of ash in wood is from 1% to 5%. The total heat of combustion of all kinds of wood, when dry, is almost exactly the same, and is that due to the 50% of carbon.

The above is from Rankine; but according to the table by S. P. Sharpless in Jour. C. I. W., iv. 36, the ash varies from 0.03% to 1.20% in American woods, and the fuel value, instead of being the same for all woods, ranges from 3667 (for white oak) to 5546 calories (for long-leaf pine) = 6600 to 9883 British thermal units for dry wood, the fuel value of 0.50 lbs. carbon being 7272 B. T. U.

**Heating Value of Wood.**—The following table is given in several books of reference, authority and quality of coal referred to not stated.

The weight of one cord of different woods (thoroughly air-dried) is about as follows:

Hickory or hard maple....	4500 lbs.	equal to	1800 lbs. coal.	(Others give 2000.)
White oak....	3850	"	1540	" " ( " 1715.)
Beech, red and black oak..	3250	"	1300	" " ( " 1450.)
Poplar, chestnut, and elm..	2350	"	940	" " ( " 1050.)
The average pine.....	2000	"	800	" " ( " 925.)

Referring to the figures in the last column, it is said:

From the above it is safe to assume that 2¼ lbs. of dry wood are equal to 1 lb. average quality of soft coal and that the full value of the same weight of different woods is very nearly the same—that is, a pound of hickory is worth no more for fuel than a pound of pine, assuming both to be dry. It is important that the wood be dry, as each 10% of water or moisture in wood will detract about 12% from its value as fuel.

Taking an average wood of the analysis C 51%, H 6.5%, O 42.0%, ash 0.5%, perfectly dry, its fuel value per pound, according to Dulong's formula,  $V =$

$\left[ 14,500 C + 62,000 \left( H - \frac{O}{8} \right) \right]$ , is 8170 British thermal units. If the wood, as ordinarily dried in air, contains 25% of moisture, then the heating value of a pound of such wood is three quarters of 8170 = 6127 heat-units, less the heat required to heat and evaporate the  $\frac{1}{4}$  lb. of water from the atmospheric temperature, and to heat the steam made from this water to the temperature of the chimney gases, say 150 heat-units per pound to heat the water to 212°, 966 units to evaporate it at that temperature, and 100 heat-units to raise the temperature of the steam to 420° F., or 1216 in all = 304 for  $\frac{1}{4}$  lb., which subtracted from the 6127, leaves 5824 heat-units as the net fuel value of the wood per pound, or about 0.4 that of a pound of carbon.

### Composition of Wood.

(Analysis of Woods, by M. Eugene Chevandier.)

Woods.	Composition.				
	Carbon.	Hydrogen.	Oxygen.	Nitrogen.	Ash.
Beech .....	49.36%	6.01%	42.69%	0.91%	1.06%
Oak .....	49.64	5.92	41.16	1.29	1.97
Birch .....	50.20	6.20	41.62	1.15	0.81
Poplar .....	49.37	6.21	41.60	0.96	1.86
Willow .....	49.96	5.96	39.56	0.96	3.37
Average .....	49.70%	6.06%	41.30%	1.05%	1.80%

The following table, prepared by M. Violette, shows the proportion of water expelled from wood at gradually increasing temperatures:

Temperature.	Water Expelled from 100 Parts of Wood.			
	Oak.	Ash.	Elm.	Walnut.
257° Fahr.....	15.26	14.78	15.32	15.55
302° Fahr.....	17.93	16.19	17.02	17.43
347° Fahr.....	32.13	21.22	36.94?	21.00
392° Fahr.....	35.80	27.51	33.38	41.77?
437° Fahr.....	44.31	33.38	40.56	36.56

The wood operated upon had been kept in store during two years. When wood which has been strongly dried by means of artificial heat is left exposed to the atmosphere, it reabsorbs about as much water as it contains in its air-dried state.

A cord of wood =  $4 \times 4 \times 8 = 128$  cu. ft. About 56% solid wood and 44% interstitial spaces. (Marcus Bull, Phila., 1829. J. C. I. W., vol. i, p. 293.)

B. E. Fernow gives the per cent of solid wood in a cord as determined officially in Prussia (J. C. I. W., vol. iii, p. 20):

- Timber cords, 74.07% = 80 cu. ft. per cord;
- Firewood cords (over 6" diam.), 69.44% = 75 cu. ft. per cord;
- "Billet" cords (over 3" diam.), 55.55% = 60 cu. ft. per cord;
- "Brush" woods less than 3" diam., 18.52%; Roots, 37.00%.

### CHARCOAL.

Charcoal is made by evaporating the volatile constituents of wood and peat, either by a partial combustion of a conical heap of the material to be charred, covered with a layer of earth, or by the combustion of a separate portion of fuel in a furnace, in which are placed retorts containing the material to be charred.

According to Peçet, 100 parts by weight of wood when charred in a heap yield from 17 to 22 parts by weight of charcoal, and when charred in a retort from 28 to 30 parts.

This has reference to the ordinary condition of the wood used in charcoal-making, in which 25 parts in 100 consist of moisture. Of the remaining 75 parts the carbon amounts to one half, or 37½% of the gross weight of the wood. Hence it appears that on an average nearly half of the carbon in the

wood is lost during the partial combustion in a heap, and about one quarter during the distillation in a retort.

To char 100 parts by weight of wood in a retort, 12½ parts of wood must be burned in the furnace. Hence in this process the whole expenditure of wood to produce from 28 to 30 parts of charcoal is 112½ parts; so that if the weight of charcoal obtained is compared with the whole weight of wood expended, its amount is from 25% to 27%; and the proportion lost is on an average 11½ + 37½ = 0.3, nearly.

According to Peclet, good wood charcoal contains about 0.07 of its weight of ash. The proportion of ash in peat charcoal is very variable, and is estimated on an average at about 0.18. (Rankine.)

Much information concerning charcoal may be found in the Journal of the Charcoal-iron Workers' Assn., vols. i. to vi. From this source the following notes have been taken:

**Yield of Charcoal from a Cord of Wood.**—From 45 to 50 bushels to the cord in the kiln, and from 30 to 35 in the meiler. Prof. Egles-ton in Trans. A. I. M. E., viii. 395, says the yield from kilns in the Lake Champlain region is often from 50 to 60 bushels for hard wood and 50 for soft wood; the average is about 50 bushels.

The apparent yield per cord depends largely upon whether the cord is a full cord of 128 cu. ft. or not.

In a four months' test of a kiln at Goodrich, Tenn., Dr. H. M. Pierce found results as follows: Dimensions of kiln—inside diameter of base, 28 ft. 8 in.; diam. at spring of arch, 26 ft. 8 in.; height of walls, 8 ft.; rise of arch, 5 ft.; capacity, 30 cords. Highest yield of charcoal per cord of wood (measured) 59.27 bushels, lowest 50.14 bushels, average 53.65 bushels.

No. of charges 12, length of each turn or period from one charging to another 11 days. (J. C. I. W., vol. vi. p. 26.)

**Results from Different Methods of Charcoal-making.**

Coaling Methods.	Character of Wood used.	Yield.		Bushels of Charcoal per Cord of Wood.	Weight in Lbs. per Bushel of Charcoal.
		In Volume per cent.	In Weight per cent.

**Consumption of Charcoal in Blast-furnaces per Ton of Pig Iron;** average consumption according to census of 1880, 1.14 tons charcoal per ton of pig. The consumption at the best furnaces is much below this average. As low as 0.853 ton, is recorded of the Morgan furnace; Bay furnace, 0.858; Elk Rapids, 0.884. (1892.)

**Absorption of Water and of Gases by Charcoal.**—Svedlius, in his hand-book for charcoal-burners, prepared for the Swedish Government, says: Fresh charcoal, also reheated charcoal, contains scarcely any water but when cooled it absorbs it very rapidly, so that after twenty-four hours, it may contain 4% to 8% of water. After the lapse of a few weeks the moisture of charcoal may not increase perceptibly, and may be estimated at 10% to 15%, or an average of 12%. A thoroughly charred piece of charcoal ought, then, to contain about 84 parts carbon, 12 parts water, 3 parts ash, and 1 part hydrogen.

M. Saussure, operating with blocks of fine boxwood charcoal, freshly burnt, found that by simply placing such blocks in contact with certain gases they absorbed them in the following proportion:

	Volumes.		Volumes.
Ammonia.....	90.00	Carbonic oxide.....	9.42
Hydrochloric acid gas.....	85.00	Oxygen.....	9.25
Sulphurous acid.....	65.00	Nitrogen.....	6.50
Sulphuretted hydrogen .....	55.00	Carburetted hydrogen.....	5.00
Nitrous oxide (laughing-gas)..	40.00	Hydrogen.....	1.75
Carbonic acid.. ..	35.00		

It is this enormous absorptive power that renders of so much value a comparatively slight sprinkling of charcoal over dead animal matter, as a preventive of the escape of odors arising from decomposition.

In a box or case containing one cubic foot of charcoal may be stored without mechanical compression a little over nine cubic feet of oxygen, representing a mechanical pressure of one hundred and twenty-six pounds to the square inch. From the store thus preserved the oxygen can be drawn by a small hand-pump.

### Composition of Charcoal Produced at Various Temperatures. (By M. Violette.)

Temperature of Carbonization.		Composition of the Solid Product.					
		Carbon.	Hydrogen.	Oxygen.	Nitrogen and Loss.	Ash.	
Cent.	Fahr.	Per cent.	Per cent.	Per cent.	Per cent.	Per cent.	
1	150°	302°	47.51	6.12	46.29	0.08	47.51
2	200	392	51.82	3.99	43.98	0.23	39.88
3	250	482	65.59	4.81	28.97	0.63	32.98
4	300.	592	73.24	4.25	21.96	0.57	24.61
5	350	662	76.64	4.14	18.44	0.61	22.42
6	432	810	81.64	4.96	15.24	1.61	15.40
7	1023	1873	81.97	2.30	14.15	1.60	15.30

The wood experimented on was that of black alder, or alder buckthorn, which furnishes a charcoal suitable for gunpowder. It was previously dried at 150 deg. C. = 302 deg. F.

### MISCELLANEOUS SOLID FUELS.

**Dust Fuel—Dust Explosions.**—Dust when mixed in air burns with such extreme rapidity as in some cases to cause explosions. Explosions of flour-mills have been attributed to ignition of the dust in confined passages. Experiments in England in 1876 on the effect of coal-dust in carrying flame in mines showed that in a dusty passage the flame from a blown-out shot may travel 50 yards. Prof. F. A. Abel (Trans. A. I. M. E., xiii. 260) says that coal-dust in mines much promotes and extends explosions, and that it may readily be brought into operation as a fiercely burning agent which will carry flame rapidly as far as its mixture with air extends, and will operate as an explosive agent though the medium of a very small proportion of fire-damp in the air of the mine. The explosive violence of the combustion of dust is largely due to the instantaneous heating and consequent expansion of the air. (See also paper on "Coal Dust as an Explosive Agent," by Dr. R. W. Raymond, Trans. A. I. M. E. 1894.) Experiments made in Germany in 1893, show that pulverized fuel may be burned without smoke, and with high economy. The fuel, instead of being introduced into the fire-box in the ordinary manner, is first reduced to a powder by pulverizers of any construction. In the place of the ordinary boiler fire-box there is a combustion chamber in the form of a closed furnace lined with fire-brick and provided with an air-injector. The nozzle throws a constant stream of fuel into the chamber, scattering it throughout the whole space of the fire-box. When this powder is once ignited, and it is very readily done by first raising the

lining to a high temperature by an open fire, the combustion continues in an intense and regular manner under the action of the current of air which carries it in. (*Mf's. Record*, April, 1893.)

Records of tests with the Wegener powdered-coal apparatus, which is now (1900) in use in Germany, are given in *Eng. News*, Sept. 16, 1897. Coal-dust fuel is now extensively used in the United States in rotary kilns for burning Portland cement.

Powdered fuel was used in the Crompton rotary puddling-furnace at Woolwich Arsenal, England, in 1873. (*Jour. I. & S. I.*, i. 1873, p. 91.)

**Peat or Turf**, as usually dried in the air, contains from 25% to 30% of water, which must be allowed for in estimating its heat of combustion. This water having been evaporated, the analysis of M. Regnault gives, in 100 parts of perfectly dry peat of the best quality: C 58%, H 6%, O 31%, Ash 5%.

In some examples of peat the quantity of ash is greater, amounting to 7% and sometimes to 11%.

The specific gravity of peat in its ordinary state is about 0.4 or 0.5. It can be compressed by machinery to a much greater density. (Rankine.)

Clark (*Steam-engine*, i. 61) gives as the average composition of dried Irish peat: C 59%, H 6%, O 30%, N 1.25%, Ash 4%.

Applying Dulong's formula to this analysis, we obtain for the heating value of perfectly dry peat 10,260 heat-units per pound, and for air-dried peat containing 25% of moisture, after making allowance for evaporating the water, 7391 heat-units per pound.

**Sawdust as Fuel.**—The heating power of sawdust is naturally the same per pound as that of the wood from which it is derived, but if allowed to get wet it is more like spent tan (which see below). The conditions necessary for burning sawdust are that plenty of room should be given it in the furnace, and sufficient air supplied on the surface of the mass. The same applies to shavings, refuse lumber, etc. Sawdust is frequently burned in saw-mills, etc., by being blown into the furnace by a fan-blast.

**Wet Tan Bark as Fuel.**—Tan, or oak bark, after having been used in the processes of tanning, is turned as fuel. The spent tan consists of the fibrous portion of the bark. According to M. Peclet, five parts of oak bark produce four parts of dry tan; and the heating power of perfectly dry tan, containing 15% of ash, is 6100 English units; whilst that of tan in an ordinary state of dryness, containing 30% of water, is only 4284 English units. The weight of water evaporated from and at 212° by one pound of tan, equivalent to these heating powers, is, for perfectly dry tan, 5.46 lbs., for tan with 30% moisture, 3.84 lbs. Experiments by Prof. R. H. Thurston (*Jour. Frank. Inst.*, 1874) gave with the Crockett furnace, the wet tan containing 59% of water, an evaporation from and at 212° F. of 4.24 lbs. of water per pound of the wet tan, and with the Thompson furnace an evaporation of 3.19 lbs. per pound of wet tan containing 55% of water. The Thompson furnace consisted of six fire-brick ovens, each 9 feet × 4 feet 4 inches, containing 234 square feet of grate in all, for three boilers with a total heating surface of 2000 square feet, a ratio of heating to grate surface of 9 to 1. The tan was fed through holes in the top. The Crockett furnace was an ordinary fire-brick furnace, 6 × 4 feet, built in front of the boiler, instead of under it, the ratio of heating surface to grate being 14.6 to 1. According to Prof. Thurston the conditions of success in burning wet fuel are the surrounding of the mass so completely with heated surfaces and with burning fuel that it may be rapidly dried, and then so arranging the apparatus that thorough combustion may be secured, and that the rapidity of combustion be precisely equal to and never exceed the rapidity of desiccation. Where this rapidity of combustion is exceeded the dry portion is consumed completely, leaving an uncovered mass of fuel which refuses to take fire.

**Straw as Fuel.** (*Eng's Mechanics*, Feb., 1893, p. 55.)—Experiments in Russia showed that winter-wheat straw, dried at 230° F., had the following composition: C, 46.1; H, 5.6; N, 0.42; O, 43.7; Ash, 4.1. Heating value in British thermal units: dry straw, 6290; with 6% water, 5770; with 10% water, 5448. With straws of other grains the heating value of dry straw ranged from 5590 for buckwheat to 6750 for flax.

Clark (*S. E.*, vol. 1, p. 62) gives the mean composition of wheat and barley straw as C, 36; H, 5; O, 38; N, 0.50; Ash, 4.75; water, 15.75, the two straws varying less than 1%. The heating value of straw of this composition, according to Dulong's formula, and deducting the heat lost in evaporating the water, is 5155 heat units. Clark erroneously gives it as 8144 heat units.

**Bagasse as Fuel in Sugar Manufacture.**—Bagasse is the name given to refuse sugar-cane, after the juice has been extracted. Prof. L. A.

Becuel, in a paper read before the Louisiana Sugar Chemists' Association, in 1892, says: "With tropical cane containing 12.5% woody fibre, a juice containing 16.13% solids, and 83.37% water, bagasse of, say, 66% and 72% mill extraction would have the following percentage composition:

	Woody Fibre.	Combustible Salts.	Water.
66% bagasse.....	37	10	53
72% bagasse.....	45	9	46

"Assuming that the woody fibre contains 51% carbon, the sugar and other combustible matters an average of 42.1%, and that 12,906 units of heat are generated for every pound of carbon consumed, the 66% bagasse is capable of generating 297,834 heat units per 100 lbs. as against 345,200, or a difference of 47,366 units in favor of the 72% bagasse.

"Assuming the temperature of the waste gases to be 450° F., that of the surrounding atmosphere and water in the bagasse at 86° F., and the quantity of air necessary for the combustion of one pound of carbon at 24 lbs., the lost heat will be as follows: In the waste gases, heating air from 86° to 450° F., and in vaporizing the moisture, etc., the 66% bagasse will require 112,546 heat units, and 116,150 for the 72% bagasse.

"Subtracting these quantities from the above, we find that the 66% bagasse will produce 185,288 available heat units per 100 lbs., or nearly 24% less than the 72% bagasse, which gives 229,050 units. Accordingly, one ton of cane of 2000 lbs. at 66% mill extraction will produce 680 lbs. bagasse, equal to 1,259,958 available heat units, while the same cane at 72% extraction will produce 560 lbs. bagasse, equal to 1,282,680 units.

"A similar calculation for the case of Louisiana cane containing 10% woody fibre, and 16% total solids in the juice, assuming 75% mill extraction, shows that bagasse from one ton of cane contains 1,573,956 heat units, from which 561,465 have to be deducted.

"This would make such bagasse worth on an average nearly 92 lbs. coal per ton of cane ground. Under fairly good conditions, 1 lb. coal will evaporate 7½ lbs. water, while the best boiler plants evaporate 10 lbs. Therefore, the bagasse from 1 ton of cane at 75% mill extraction should evaporate from 689 lbs. to 919 lbs. of water. The juice extracted from such cane would under these conditions contain 1260 lbs. of water. If we assume that the water added during the process of manufacture is 10% (by weight) of the juice made, the total water handled is 1410 lbs. From the juice represented in this case, the commercial massecuite would be about 15% of the weight of the original mill juice, or say 225 lbs. Said mill juice 1500 lbs., plus 10%, equals 1650 lbs. liquor handled; and 1650 lbs., minus 225 lbs., equals 1425 lbs., the quantity of water to be evaporated during the process of manufacture. To effect a 7½-lb. evaporation requires 190 lbs. of coal, and 142½ lbs. for a 10-lb. evaporation.

"To reduce 1650 lbs. of juice to syrup of, say, 27° Baumé, requires the evaporation of 1170 lbs. of water, leaving 480 lbs. of syrup. If this work be accomplished in the open air, it will require about 156 lbs. of coal at 7½ lbs. boiler evaporation, and 117 at 10 lbs. evaporation.

"With a double effect the fuel required would be from 59 to 78 lbs., and with a triple effect, from 36 to 52 lbs.

"To reduce the above 480 lbs. of syrup to the consistency of commercial massecuite means the further evaporation of 255 lbs. of water, requiring the expenditure of 34 lbs. coal at 7½ lbs. boiler evaporation, and 25½ lbs. with a 10-lb. evaporation. Hence, to manufacture one ton of cane into sugar and molasses, it will take from 145 to 190 lbs. additional coal to do the work by the open evaporator process; from 85 to 112 lbs. with a double effect, and only 7½ lbs. evaporation in the boilers, while with 10 lbs. boiler evaporation the bagasse alone is capable of furnishing 8% more heat than is actually required to do the work. With triple-effect evaporation depending on the excellence of the boiler plant, the 1425 lbs. of water to be evaporated from the juice will require between 62 and 86 lbs. of coal. These values show that from 6 to 30 lbs. of coal can be spared from the value of the bagasse to run engines, grind cane, etc.

"It accordingly appears," says Prof. Becuel, "that with the best boiler plants, those taking up all the available heat generated, by using this heat economically the bagasse can be made to supply all the fuel required by our sugar-houses."

**PETROLEUM.**

**Products of the Distillation of Crude Petroleum.**

Crude American petroleum of sp. gr. 0.800 may be split up by fractional distillation as follows (Robinson's Gas and Petroleum Engines):

Temp. of Distillation Fahr.	Distillate.	Percentages.	Specific Gravity.	Flashing Point. Deg. F.
113°	Rhigolene. }	traces.	.590 to .625	.....
113 to 140°	Chymogene. }			
140 to 158°	Gasolene (petroleum spirit)...	1.5	.636 to .657	.....
158 to 248°	Benzine, naphtha C, benzolene.	10.	.680 to .700	14
248°	} Benzine, naphtha B .....	2.5	.714 to .718	.....
to		} " " A.....	2.	.725 to .737
347°	{ Polishing oils. ....		.....	.....
338° and upwards. }	Kerosene (lamp-oil).....	50.	.802 to .820	100 to 122
	482°	Lubricating oil.....	15.	.850 to .915
.....	Paraffine wax.....	2.	.....	.....
.....	Residue and Loss.....	16.	.....	.....

**Lima Petroleum**, produced at Lima, Ohio, is of a dark green color, very fluid, and marks 48° Baumé at 15° C. (sp. gr., 0.792).

The distillation in fifty parts, each part representing 2% by volume, gave the following results :

Per cent.	Sp. Gr.										
2	0.680	18	0.720	34	0.764	50	0.802	68	0.820	88	0.815
4	.683	20	.728	36	.768	52		70	.825	90	.815
6	.685	22	.730	38	.772	to	} .806	72	.830	} 92	} Residuum
8	.690	24	.735	40	.778	58			73		
10	.694	26	.740	42	.782	60	.800	76	.810	to	
12	.698	28	.742	44	.788	62	.804	78	.820	100	
14	.700	30	.746	46	.792	64	.808	82	.818		
16	.706	32	.760	48	.800	66	.812	86	.816		

RETURNS.

16 per cent naphtha, 70° Baumé. 6 per cent paraffine oil.  
 68 " burning oil. 10 " residuum.

The distillation started at 23° C., this being due to the large amount of naphtha present, and when 60% was reached, at a temperature of 310° C., the hydrocarbons remaining in the retort were dissociated, then gases escaped, lighter distillates were obtained, and, as usual in such cases, the temperature decreased from 310° C. down gradually to 200° C., until 75% of oil was obtained, and from this point the temperature remained constant until the end of the distillation. Therefore these hydrocarbons in *statu moriendi* absorbed much heat. (*Jour. Am. Chem. Soc.*)

**Value of Petroleum as Fuel.**—Thos. Urquhart, of Russia (*Proc. Inst. M. E.*, Jan. 1889), gives the following table of the theoretical evaporative power of petroleum in comparison with that of coal, as determined by Messrs. Favre & Silbermann:

Fuel.	Specific Gravity at 32° F., Water = 1.000.	Chem. Comp.			Heating-power, British Thermal Units.	Theoret. Evap., lbs. Water per lb. Fuel, from and at 212° F.
		C.	H.	O.		
Penna. heavy crude oil....	0.886	p. c. 84.9	p. c. 13.7	p. c. 1.4	Units. 20,736	lbs. 21.48
Caucasian light crude oil..	0.884	86.3	13.6	0.1	22,027	22.79
" heavy " " ..	0.938	86.6	12.3	1.1	20,138	20.85
Petroleum refuse.....	0.928	87.1	11.7	1.2	19,832	20.53
Good English Coal, Mean of 98 Samples.....	1.380	80.0	5.0	8.0	14,112	14.61

In experiments on Russian railways with petroleum as fuel Mr. Urquhart obtained an actual efficiency equal to 82% of the theoretical heating-value. The petroleum is fed to the furnace by means of a spray-injector driven by steam. An induced current of air is carried in around the injector-nozzle, and additional air is supplied at the bottom of the furnace.

**Oil vs. Coal as Fuel.** (*Iron Age*, Nov. 2, 1893.)—Test by the Twin City Rapid Transit Company of Minneapolis and St. Paul. This test showed that with the ordinary Lima oil weighing 6 6/10 pounds per gallon, and costing 2¼ cents per gallon, and coal that gave an evaporation of 7½ lbs. of water per pound of coal, the two fuels were equally economical when the price of coal was \$3.85 per ton of 2000 lbs. With the same coal at \$2.00 per ton, the coal was 37% more economical, and with the coal at \$4.85 per ton, the coal was 20% more expensive than the oil. These results include the difference in the cost of handling the coal, ashes, and oil.

In 1892 there were reported to the Engineers' Club of Philadelphia some comparative figures, from tests undertaken to ascertain the relative value of coal, petroleum, and gas.

	Lbs. Water, from and at 212° F.
1 lb. anthracite coal evaporated.....	9.70
1 lb. bituminous coal .....	10.14
1 lb. fuel oil, 36° gravity .....	16.48
1 cubic foot gas, 20 C. P.....	1.28

The gas used was that obtained in the distillation of petroleum, having about the same fuel-value as natural or coal-gas of equal candle-power.

Taking the efficiency of bituminous coal as a basis, the calorific energy of petroleum is more than 60% greater than that of coal; whereas, theoretically, petroleum exceeds coal only about 45%—the one containing 14,560 heat-units, and the other 21,000.

**Crude Petroleum vs. Indiana Block Coal for Steam-raising at the South Chicago Steel Works.** (E. C. Potter, *Trans. A. I. M. E.*, xvii, 807.)—With coal, 14 tubular boilers 16 ft. × 5 ft. required 25 men to operate them; with fuel oil, 6 men were required, a saving of 19 men at \$2 per day, or \$33 per day.

For one week's work 2731 barrels of oil were used, against 848 tons of coal required for the same work, showing 3.22 barrels of oil to be equivalent to 1 ton of coal. With oil at 60 cents per barrel and coal at \$2.15 per ton, the relative cost of oil to coal is as \$1.93 to \$2.15. No evaporation tests were made.

**Petroleum as a Metallurgical Fuel.**—C. E. Felton (*Trans. A. I. M. E.*, xvii, 803) reports a series of trials with oil as fuel in steel-heating and open-hearth steel-furnaces, and in raising steam, with results as follows: 1. In a run of six weeks the consumption of oil, partly refined (the paraffine and some of the naphtha being removed), in heating 14-inch ingots in Siemens furnaces was about 6½ gallons per ton of blooms. 2. In melting in a 30-ton open-hearth furnace 48 gallons of oil were used per ton of ingots. 3. In a six weeks' trial with Lima oil from 47 to 54 gallons of oil were required per ton of ingots. 4. In a six months' trial with Siemens heating-furnaces the consumption of Lima oil was 6 gallons per ton of ingots. Under the most favorable circumstances, charging hot ingots and running full capacity, 4½ to 5 gallons per ton were required. 5. In raising steam in two 100-H.P. tubular boilers, the feed-water being supplied at 160° F., the average evaporation was about 12 pounds of water per pound of oil, the best 12 hours' work being 16 pounds.

In all of the trials the oil was vaporized in the Archer producer, an apparatus for mixing the oil and superheated steam, and heating the mixture to a high temperature. From 0.5 lb. to 0.75 lb. of pea-coal was used per gallon of oil in the producer itself.

### FUEL GAS.

The following notes are extracted from a paper by W. J. Taylor on "The Energy of Fuel" (*Trans. A. I. M. E.*, xviii, 205):

**Carbon Gas.**—In the old Siemens producer, practically, all the heat of primary combustion—that is, the burning of solid carbon to carbon monoxide, or about 30% of the total carbon energy—was lost, as little or no steam was used in the producer, and nearly all the sensible heat of the gas was dissipated in its passage from the producer to the furnace, which was usually placed at a considerable distance.

Modern practice has improved on this plan, by introducing steam with the

air blown into the producer, and by utilizing the sensible heat of the gas in the combustion-furnace. It ought to be possible to oxidize one out of every four lbs. of carbon with oxygen derived from water-vapor. The thermic reactions in this operation are as follows:

	Heat-units.
4 lbs. C burned to CO (3 lbs. gasified with air and 1 lb. with water) develop.....	17,600
1.5 lbs. of water (which furnish 1.33 lbs. of oxygen to combine with 1 lb. of carbon) absorb by dissociation.....	10,333
The gas, consisting of 9.333 lbs. CO, 0.167 lb. H, and 13.39 lbs. N, heated 600°, absorbs.....	3,748
Leaving for radiation and loss .....	3,519
	17,600

The steam which is blown into a producer with the air is almost all condensed into finely-divided water before entering the fuel, and consequently is considered as water in these calculations.

The 1.5 lbs. of water liberates .167 lb. of hydrogen, which is delivered to the gas, and yields in combustion the same heat that it absorbs in the producer by dissociation. According to this calculation, therefore, 60% of the heat of primary combustion is theoretically recovered by the dissociation of steam, and, even if all the sensible heat of the gas be counted, with radiation and other minor items, as loss, yet the gas must carry  $4 \times 14,500 - (3,748 + 3,519) = 50,733$  heat-units, or 87% of the calorific energy of the carbon. This estimate shows a loss in conversion of 13%, without crediting the gas with its sensible heat, or charging it with the heat required for generating the necessary steam, or taking into account the loss due to oxidizing some of the carbon to CO<sub>2</sub>. In good producer-practice the proportion of CO<sub>2</sub> in the gas represents from 4% to 7% of the C burned to CO<sub>2</sub>, but the extra heat of this combustion should be largely recovered in the dissociation of more water-vapor, and therefore does not represent as much loss as it would indicate. As a conveyer of energy, this gas has the advantage of carrying 4.46 lbs. less nitrogen than would be present if the fourth pound of coal had been gasified with air; and in practical working the use of steam reduces the amount of clinkering in the producer.

**Anthracite Gas.**—In anthracite coal there is a volatile combustible varying in quantity from 1.5% to over 7%. The amount of energy derived from the coal is shown in the following theoretical gasification made with coal of assumed composition: Carbon, 85%; vol. HC, 5%; ash, 10%; 80 lbs. carbon assumed to be burned to CO; 5 lbs. carbon burned to CO<sub>2</sub>; three fourths of the necessary oxygen derived from air, and one fourth from water.

Process.	Products.		
	Pounds.	Cubic Feet.	Anal. by Vol.
80 lbs. C burned to.... CO	186.66	2529.24	33.4
5 lbs. C burned to.....CO <sub>2</sub>	18.33	157.64	2.0
5 lbs. vol. HC (distilled).....	5.00	116.60	1.6
120 lbs. oxygen are required, of which			
30 lbs. from H <sub>2</sub> O liberate.....H	3.75	712.50	9.4
90 lbs. from air are associated with N	301.05	4064.17	53.6
	514.79	7580.15	100.0

Energy in the above gas obtained from 100 lbs. anthracite:

186.66 lbs CO.....	807,304 heat-units.
5.00 " CH <sub>4</sub> .....	117,500 "
3.75 " H.....	232,500 "

	1,157,304	"
Total energy in gas per lb.....	2,248	"
" " " 100 lbs. of coal.....	1,349,500	"
Efficiency of the conversion .....	86%.	

The sum of CO and H exceeds the results obtained in practice. The sensible heat of the gas will probably account for this discrepancy, and, therefore, it is safe to assume the possibility of delivering at least 82% of the energy of the anthracite.

**Bituminous Gas.**—A theoretical gasification of 100 lbs. of coal, containing 55% of carbon and 32% of volatile combustible (which is above the average of Pittsburgh coal), is made in the following table. It is assumed that 50 lbs. of C are burned to CO and 5 lbs. to CO<sub>2</sub>; one fourth of the O is

derived from steam and three fourths from air; the heat value of the volatile combustible is taken at 20,000 heat-units to the pound. In computing volumetric proportions all the volatile hydrocarbons, fixed as well as condensing, are classed as marsh-gas, since it is only by some such tentative assumption that even an approximate idea of the volumetric composition can be formed. The energy, however, is calculated from weight:

Process.	Products.		
	Pounds.	Cubic Feet.	Anal. by Vol.
50 lbs. C burned to.... CO	116.66	1580.7	27.8
5 lbs. C burned to..... CO <sub>2</sub>	18.33	157.6	2.7
32 lbs. vol. HC (distilled).....	32.00	746.2	13.2
80 lbs. O are required, of which 20 lbs., derived from H <sub>2</sub> O, liberate..... H	2.5	475.0	8.3
60 lbs. O, derived from air, are asso- ciated with..... N	200.70	2709.4	47.8
	<u>370.19</u>	<u>5668.9</u>	<u>99.8</u>
Energy in 116.66 lbs. CO..	504,554	heat-units.	
“ “ 32.00 lbs. vol. HC....	640,000	“	
“ “ 2.50 lbs. H.....	155,000	“	
	<u>1,299,554</u>	“	
Energy in coal.....	1,437,500	“	
Per cent of energy delivered in gas.....			90.0
Heat-units in 1 lb. of gas.....			3,484

**Water-gas.**—Water-gas is made in an intermittent process, by blowing up the fuel-bed of the producer to a high state of incandescence (and in some cases utilizing the resulting gas, which is a lean producer-gas), then shutting off the air and forcing steam through the fuel, which dissociates the water into its elements of oxygen and hydrogen, the former combining with the carbon of the coal, and the latter being liberated.

This gas can never play a very important part in the industrial field, owing to the large loss of energy entailed in its production, yet there are places and special purposes where it is desirable, even at a great excess in cost per unit of heat over producer-gas; for instance, in small high-temperature furnaces, where much regeneration is impracticable, or where the “blow-up” gas can be used for other purposes instead of being wasted.

The reactions and energy required in the production of 1000 feet of water-gas, composed, theoretically, of equal volumes of CO and H, are as follows:

500 cubic feet of H weigh.....	2.635 lbs.
500 cubic feet of CO weigh.....	36.89 “

Total weight of 1000 cubic feet..... 39.525 lbs.

Now, as CO is composed of 12 parts C to 16 of O, the weight of C in 36.89 lbs is 15.81 lbs. and of O 21.08 lbs. When this oxygen is derived from water it liberates, as above, 2.635 lbs. of hydrogen. The heat developed and absorbed in these reactions (roughly, as we will not take into account the energy required to elevate the coal from the temperature of the atmosphere to say 1800°) is as follows:

	Heat units.
2.635 lbs. H absorb in dissociation from water $2.635 \times 62,000..$	= 163,370
15.81 lbs. C burned to CO develops $15.81 \times 4400.....$	= 69,564
Excess of heat-absorption over heat-development .....	= 93,806

If this excess could be made up from C burnt to CO<sub>2</sub> without loss by radiation, we would only have to burn an additional 4.83 lbs. C to supply this heat, and we could then make 1000 feet of water-gas from 20.64 lbs. of carbon (equal 24 lbs. of 85% coal). This would be the perfection of gas-making, as the gas would contain really the same energy as the coal; but instead, we require in practice more than double this amount of coal, and do not deliver more than 50% of the energy of the fuel in the gas, because the supporting heat is obtained in an indirect way and with imperfect combustion. Besides this, it is not often that the sum of the CO and H exceed 90%, the balance being CO<sub>2</sub> and N. But water-gas should be made with much less loss of energy by burning the “blow-up” (producer) gas in brick regenerators, the stored-up heat of which can be returned to the producer by the air used in blowing-up.

The following table shows what may be considered average volumetric

analyses, and the weight and energy of 1000 cubic feet, of the four types of gases used for heating and illuminating purposes:

	Natural Gas.	Coal-gas.	Water-gas.	Producer-gas.	
				Anthra.	Bitu.
CO.....	0.50	6.0	45.0	27.0	27.0

Approximately 30,000 cubic feet of gas have the heating power of one ton of coal.

**Producer-gas from One Ton of Coal.**

(W. H. Blauvelt, Trans. A. I. M. E., xviii. 614.)

Analysis by Vol.	Per Cent.	Cubic Feet.	Lbs.	Equal to—
CO.....	25.3	33,213.84	2451.20	1050.51 lbs. C + 1400.7 lbs. O.
H.....	9.2	12,077.76	63.56	63.56 " H.
CH <sub>4</sub> .....	3.1	4,069.68	174.66	174.66 " CH <sub>4</sub> .
C <sub>2</sub> H <sub>4</sub> .....	0.8	1,050.24	77.78	77.78 " C <sub>2</sub> H <sub>4</sub> .
CO <sub>2</sub> .....	3.4	4,463.52	519.02	141.54 " C + 377.44 lbs. O.
N (by difference).	58.2	76,404.96	5659.63	7350.17 " Air.
	100.0	131,280.00	8945.85	

Calculated upon this basis, the 131,280 ft. of gas from the ton of coal contained 20,311,162 B.T.U., or 155 B.T.U. per cubic ft., or 2270 B.T.U. per lb.

The composition of the coal from which this gas was made was as follows: Water, 1.26%; volatile matter, 36.22%; fixed carbon, 57.98%; sulphur, 0.70%; ash, 3.78%. One ton contains 1159.6 lbs. carbon and 724.4 lbs. volatile combustible, the energy of which is 31,302,200 B.T.U. Hence, in the processes of gasification and purification there was a loss of 35.2% of the energy of the coal.

The composition of the hydrocarbons in a soft coal is uncertain and quite complex; but the ultimate analysis of the average coal shows that it approaches quite nearly to the composition of CH<sub>4</sub> (marsh-gas).

Mr. Blauvelt emphasizes the following points as highly important in soft-coal producer-practice:

First. That a large percentage of the energy of the coal is lost when the gas is made in the ordinary low producer and cooled to the temperature of the air before being used. To prevent these sources of loss, the producer should be placed so as to lose as little as possible of the sensible heat of the gas, and prevent condensation of the hydrocarbon vapors. A high fuel-bed should be carried, keeping the producer cool on top, thereby preventing the breaking-down of the hydrocarbons and the deposit of soot, as well as keeping the carbonic acid low.

Second. That a producer should be blown with as much steam mixed with the air as will maintain incandescence. This reduces the percentage of nitrogen and increases the hydrogen, thereby greatly enriching the gas. The temperature of the producer is kept down, diminishing the loss of heat by radiation through the walls, and in a large measure preventing clinkers.

**The Combustion of Producer-gas.** (H. H. Campbell, Trans. A. I. M. E., xix, 128.)—The combustion of the components of ordinary producer-gas may be represented by the following formulæ:

AVERAGE COMPOSITION BY VOLUME OF PRODUCER-GAS: A, MADE WITH OPEN GRATES, NO STEAM IN BLAST; B, OPEN GRATES, STEAM-JET IN BLAST. 10 SAMPLES OF EACH.

	CO <sub>2</sub> .	O.	C <sub>2</sub> H <sub>4</sub> .	CO.	H.	CH <sub>4</sub> .	N.
A min .....	3.6	0.4	0.2	20.0	5.3	3.0	58.7
A max .....	5.6	0.4	0.4	24.8	8.5	5.2	64.4
A average...	4.84	0.4	0.34	22.1	6.8	3.74	61.78
B min .....	4.6	0.4	0.2	20.8	6.9	2.2	57.2

B average...	5.3	0.54	0.36	22.74	8.37	2.56	60.13

The coal used contained carbon 82%, hydrogen 4.7%.

The following are analyses of products of combustion:

	CO <sub>2</sub> .	O.	CO.	CH <sub>4</sub> .	H.	N.
Minimum.....	15.2	0.2	trace.	trace.	trace.	80.1
Maximum.....	17.2	1.6	2.0	0.6	2.0	83.6
Average.....	16.3	0.8	0.4	0.1	0.2	82.2

**Use of Steam in Producers and in Boiler-furnaces.** (R. W. Raymond, Trans. A. I. M. E., xx, 635.)—No possible use of steam can cause a gain of heat. If steam be introduced into a bed of incandescent carbon it is decomposed into hydrogen and oxygen.

The heat absorbed by the reduction of one pound of steam to hydrogen is much greater in amount than the heat generated by the union of the oxygen thus set free with carbon, forming either carbonic oxide or carbonic acid. Consequently, the effect of steam alone upon a bed of incandescent fuel is to chill it. In every water-gas apparatus, designed to produce by means of the decomposition of steam a fuel-gas relatively free from nitrogen, the loss of heat in the producer must be compensated by some reheating device.

This loss may be recovered if the hydrogen of the steam is subsequently burned, to form steam again. Such a combustion of the hydrogen is contemplated, in the case of fuel-gas, as secured in the subsequent use of that gas. Assuming the oxidation of H to be complete, the use of steam will cause neither gain nor loss of heat, but a simple transference, the heat absorbed by steam decomposition being restored by hydrogen combustion. In practice, it may be doubted whether this restoration is ever complete. But it is certain that an excess of steam would defeat the reaction altogether, and that there must be a certain proportion of steam, which permits the realization of important advantages, without too great a net loss in heat.

The advantage to be secured (in boiler furnaces using small sizes of anthracite) consists principally in the transfer of heat from the lower side of the fire, where it is not wanted, to the upper side, where it is wanted. The decomposition of the steam below cools the fuel and the grate-bars, whereas a blast of air alone would produce, at that point, intense combustion (forming at first CO<sub>2</sub>), to the injury of the grate, the fusion of part of the fuel, etc.

The proportion of steam most economical is not easily determined. The temperature of the steam itself, the nature of the fuel mixture, and the use or non-use of auxiliary air-supply, introduced into the gases above or

beyond the fire-bed, are factors affecting the problem. (See Trans. A. I. M. E., xx. 625.)

**Gas Analyses by Volume and by Weight.**—To convert an analysis of a mixed gas by volume into analysis by weight: Multiply the percentage of each constituent gas by the density of that gas (see p. 166). Divide each product by the sum of the products to obtain the percentages by weight.

**Gas-fuel for Small Furnaces.**—E. P. Reichhelm (*Am. Mach.*, Jan. 10, 1895) discusses the use of gaseous fuel for forge fires, for drop-forging, in annealing-ovens and furnaces for melting brass and copper, for case-hardening, muffle-furnaces, and kilns. Under ordinary conditions, in such furnaces he estimates that the loss by draught, radiation, and the heating of space not occupied by work is, with coal, 80%, with petroleum 70%, and with gas above the grade of producer-gas 25%. He gives the following table of comparative cost of fuels, as used in these furnaces:

Kind of Gas.	No. of Heat-units in 1,000 cu. ft. used.	No. of Heat-units in Furnaces after Deducting 25% Loss.	Average Cost per 1,000 Ft.	Cost of 1,000 Heat-units Obtained in Furnaces.
Natural gas.....	1,000,000	750,000	.....	.....
Coal-gas, 20 candle-power.....	675,000	506,250	\$1.25	\$2.46
Carburetted water-gas.....	646,000	484,500	1.00	2.06
Gasolene gas, 20 candle-power.....	690,000	517,500	.90	1.73
Water-gas from coke.....	313,000	234,750	.40	1.70
Water-gas from bituminous coal.....	377,000	282,750	.45	1.59
Water-gas and producer-gas mixed....	185,000	138,750	.20	1.44
Producer-gas.....	150,000	112,500	.15	1.33
Naphtha-gas, fuel 2½ gals. per 1000 ft..	306,367	229,774	.15	.65
Coal, \$4 per ton, per 1,000,000 heat-units utilized ..				.73
Crude petroleum, 3 cts. per gal., per 1,000,000 heat-units. ....				.73

Mr. Reichhelm gives the following figures from practice in melting brass with coal and with naphtha converted into gas: 1800 lbs. of metal require 1080 lbs. of coal, at \$4.65 per ton, equal to \$2 51, or, say, 15 cents per 100 lbs. Mr. T.'s report: 2500 lbs. of metal require 47 gals. of naphtha, at 6 cents per gal., equal to \$2.82, or, say, 11¼ cents per 100 lbs.

## ILLUMINATING-GAS.

**Coal-gas** is made by distilling bituminous coal in retorts. The retort is usually a long horizontal semi-cylindrical or  $\square$  shaped chamber, holding from 160 to 300 lbs. of coal. The retorts are set in "benches" of from 3 to 9, heated by one fire, which is generally of coke. The vapors distilled from the coal are converted into a fixed gas by passing through the retort, which is heated almost to whiteness.

The gas passes out of the retort through an "ascension-pipe" into a long horizontal pipe called the hydraulic main, where it deposits a portion of the tar it contains; thence it goes into a condenser, a series of iron tubes surrounded by cold water, where it is freed from condensable vapors, as ammonia-water, then into a washer, where it is exposed to jets of water, and into a scrubber, a large chamber partially filled with trays made of wood or iron, containing coke, fragments of brick or paving-stones, which are wet with a spray of water. By the washer and scrubber the gas is freed from the last portion of tar and ammonia and from some of the sulphur compounds. The gas is then finally purified from sulphur compounds by passing it through lime or oxide of iron. The gas is drawn from the hydraulic main and forced through the washer, scrubber, etc., by an exhaustor or gas pump.

The kind of coal used is generally caking bituminous, but as usually this coal is deficient in gases of high illuminating power, there is added to it a portion of cannel coal or other enricher.

The following table, abridged from one in Johnson's Cyclopaedia, shows the analysis, candle power, etc., of some gas-coals and enrichers:

Gas-coals, etc.	Vol. Matter.	Fixed Carb.	Ash.	Gas per ton of 2240 lbs. in cu. ft.	Cand.-pow'r of Gas.	Coke per ton of 2240 lbs.		Gas purified by 1 bush. of lime, in cu. ft.
						lbs.	bush.	
Pittsburgh, Pa .....	36.76	51.93	7.07	.....	.....	.....	..	.....
Westmoreland, Pa .....	36.00	58.00	6.00	10,642	16.62	1544	40	6420
Sterling, O. ....	37.50	56.90	5.60	10,528	18.81	1480	36	3993
Despard, W. Va. ....	40.00	53.30	6.70	10,765	20.41	1540	36	2494
Darlington, O. ....	43.00	40.00	17.00	9,800	34.98	1320	32	2806
Petonia, W. Va. ....	46.00	41.00	13.00	13,200	42.79	1380	32	4510
Grahamite, W. Va. ....	53.50	44.50	2.00	15,000	28.70	1056	44	....

The products of the distillation of 100 lbs. of average gas-coal are about as follows. They vary according to the quality of coal and the temperature of distillation.

Coke, 64 to 65 lbs.; tar, 6.5 to 7.5 lbs.; ammonia liquor, 10 to 12 lbs.; purified gas, 15 to 12 lbs.; impurities and loss, 4.5% to 3.5%.

The composition of the gas by volume ranges about as follows: Hydrogen, 38% to 48%; carbonic oxide, 2% to 14%; marsh-gas (Methane,  $\text{CH}_4$ ), 43% to 31%; heavy hydrocarbons ( $\text{C}_n\text{H}_{2n}$ , ethylene, propylene, benzole vapor, etc.), 7.5% to 4.5%; nitrogen, 1% to 3%.

In the burning of the gas the nitrogen is inert; the hydrogen and carbonic oxide give heat but no light. The luminosity of the flame is due to the decomposition by heat of the heavy hydrocarbons into lighter hydrocarbons and carbon, the latter being separated in a state of extreme subdivision. By the heat of the flame this separated carbon is heated to intense whiteness, and the illuminating effect of the flame is due to the light of incandescence of the particles of carbon.

The attainment of the highest degree of luminosity of the flame depends upon the proper adjustment of the proportion of the heavy hydrocarbons (with due regard to their individual character) to the nature of the diluent mixed therewith.

Investigations of Percy F. Frankland show that mixtures of ethylene and hydrogen cease to have any luminous effect when the proportion of ethylene does not exceed 10% of the whole. Mixtures of ethylene and carbonic oxide cease to have any luminous effect when the proportion of the former does not exceed 20%, while all mixtures of ethylene and marsh-gas have more or less luminous effect. The luminosity of a mixture of 10% ethylene and 90% marsh-gas being equal to about 18 candles, and that of one of 20% ethylene and 80% marsh-gas about 25 candles. The illuminating effect of marsh-gas alone, when burned in an argand burner, is by no means inconsiderable.

For further description, see the Treatises on Gas by King, Richards, and Hughes; also Appleton's Cyc. Mech., vol. i. p. 900.

**Water-gas.**—Water-gas is obtained by passing steam through a bed of coal, coke, or charcoal heated to redness or beyond. The steam is decomposed, its hydrogen being liberated and its oxygen burning the carbon of the fuel, producing carbonic-oxide gas. The chemical reaction is,  $\text{C} + \text{H}_2\text{O} = \text{CO} + 2\text{H}$ , or  $2\text{C} + 2\text{H}_2\text{O} = \text{C} + \text{CO}_2 + 4\text{H}$ , followed by a splitting up of the  $\text{CO}_2$ , making  $2\text{CO} + 4\text{H}$ . By weight the normal gas  $\text{CO} + 2\text{H}$  is composed of  $\text{C} + \text{O} + \text{H} = 28$  parts CO and 2 parts H, or 93.33% CO and 6.67% H;

$\frac{12}{12} + \frac{16}{16} + \frac{2}{2}$

by volume it is composed of equal parts of carbonic oxide and hydrogen. Water-gas produced as above described has great heating-power, but no illuminating-power. It may, however, be used for lighting by causing it to heat to whiteness some solid substance, as is done in the Welsbach incandescent light.

An illuminating-gas is made from water-gas by adding to it hydrocarbon gases or vapors, which are usually obtained from petroleum or some of its products. A history of the development of modern illuminating water-gas processes, together with a description of the most recent forms of apparatus, is given by Alex. C. Humphreys, in a paper on "Water-gas in the United States," read before the Mechanical Section of the British Association for Advancement of Science, in 1889. After describing many earlier patents, he states that success in the manufacture of water-gas may be said to date

from 1874, when the process of T. S. C. Lowe was introduced. All the later most successful processes are the modifications of Lowe's, the essential features of which were "an apparatus consisting of a generator and superheater internally fired; the superheater being heated by the secondary combustion from the generator, the heat so stored up in the loose brick of the superheater being used, in the second part of the process, in the fixing or rendering permanent of the hydrocarbon gases; the second part of the process consisting in the passing of steam through the generator fire, and the admission of oil or hydrocarbon at some point between the fire of the generator and the loose filling of the superheater."

The water-gas process thus has two periods: first the "blow," during which air is blown through the bed coal in the generator, and the partially burned gaseous products are completely burned in the superheater, giving up a great portion of their heat to the fire-brick work contained in it, and then pass out to a chimney; second, the "run" during which the air blast is stopped, the opening to the chimney closed, and steam is blown through the incandescent bed of fuel. The resulting water-gas passing into the carburetting chamber in the base of the superheater is there charged with hydrocarbon vapors, or spray (such as naphtha and other distillates or crude oil) and passes through the superheater, where the hydrocarbon vapors become converted into fixed illuminating gases. From the superheater the combined gases are passed, as in the coal-gas process, through washers, scrubbers, etc., to the gas-holder. In this case, however, there is no ammonia to be removed.

The specific gravity of water-gas increases with the increase of the heavy hydrocarbons which give it illuminating power. The following figures, taken from different authorities, are given by F. H. Shelton in a paper on Water-gas, read before the Ohio Gas Light Association, in 1894:

Candle-power ...	19.5	20.	22.5	24.	25.4	26.3	28.3	29.6	.30 to 31.9
Sp. gr. (Air = 1)...	.571	.630	.589	.60 to .67	.64	.602	.70	.65	.65 to .71

**Analyses of Water-gas and Coal-gas Compared.**

The following analyses are taken from a report of Dr. Gideon E. Moore on the Granger Water-gas, 1885:

	Composition by Volume.			Composition by Weight.

The heating values (B. T. U.) of the gases are calculated from the analysis by weight, by using the multipliers given below (computed from results of

J. Thomsen), and multiplying the result by the weight of 1 cu. ft. of the gas at 62° F., and atmospheric pressure.

The flame temperatures (theoretical) are calculated on the assumption of complete combustion of the gases in air, without excess of air.

The candle-power was determined by photometric tests, using a pressure of  $\frac{1}{2}$ -in. water-column, a candle consumption of 120 grains of spermaceti per hour, and a meter rate of 5 cu. ft. per hour, the result being corrected for a temperature of 62° F. and a barometric pressure of 30 in. It appears that the candle-power may be regulated at the pleasure of the person in charge of the apparatus, the range of candle-power being from 20 to 29 candles, according to the manipulation employed.

### Calorific Equivalents of Constituents of Illuminating-gas.

**Efficiency of a Water-gas Plant.**—The practical efficiency of an illuminating water-gas setting is discussed in a paper by A. G. Glasgow (Proc. Am. Gaslight Assn., 1890), from which the following is abridged :

The results refer to 1000 cu. ft. of unpurified carburetted gas, reduced to 60° F. The total anthracite charged per 1000 cu. ft. of gas was 33.4 lbs., ash and unconsumed coal removed 9.9 lbs., leaving total combustible consumed 23.5 lbs., which is taken to have a fuel-value of 14500 B. T. U. per pound, or a total of 340,750 heat-units.

		Composi- tion by Volume.	Weight per 100 cu. ft.	Composi- tion by Weight.	Specific Heat.

The heat energy absorbed by the apparatus is  $23.5 \times 14,500 = 340,750$  heat-units = *A*. Its disposition is as follows :

*E*, the energy of the CO produced;

*C*, the energy absorbed in the decomposition of the steam;

*D*, the difference between the sensible heat of the escaping illuminating-gases and that of the entering oil;

*E*, the heat carried off by the escaping blast products;

*F*, the heat lost by radiation from the shells;

*G*, the heat carried away from the shells by convection (air-currents);

*H*, the heat rendered latent in the gasification of the oil;

*I*, the sensible heat in the ash and unconsumed coal recovered from the generator.

The heat equation is  $A = B + C + D + E + F + G + H + I$ ; *A* being known. A comparison of the CO in Tables I and II show that  $\frac{280}{434}$ , or 64.5%

of the volume of carburetted gas is pure water-gas, distributed thus: CO<sub>2</sub>, 2.3%; CO, 28.0%; H, 33.4%; N, 0.8%; = 64.5%. 1 lb. of CO at 60° F. = 13.531 cu. ft. CO per 1000 cu. ft. of gas =  $280 \div 13.531 = 20.694$  lbs. Energy of the CO =  $20.694 \times 4395.6 = 91,043$  heat-units, = *B*. 1 lb. of H at 60° F. = 189.2 cu. ft. H per M of gas =  $334 \div 189.2 = 1.7653$  lbs. Energy of the H per lb. (according to Thomsen, considering the steam generated by its combustion to be condensed to water at 75° F.) = 61,524 B. T. U. In Mr. Glasgow's experiments the steam entered the generator at 331° F.; the heat required to raise the product of combustion of 1 lb. of H, viz., 8.98 lbs. H<sub>2</sub>O, from water at 75° to steam at 331° must therefore be deducted from Thomsen's figure, or  $61,524 - (8.98 \times 1140.2) = 51,285$  B. T. U. per lb. of H. Energy of the H, then, is  $1.7653 \times 51,285 = 90,533$  heat-units, = *C*. The heat lost due to the sensible heat in the illuminating-gases, their temperature being 1450° F., and that of the entering oil 235° F., is  $48.29$  (weight)  $\times .45786$  sp. heat  $\times 1215$  (rise of temperature) = 26,864 heat-units = *D*.

(The specific heat of the entering oil is approximately that of the issuing gas.)

The heat carried off in 1000 cu. ft. of the escaping blast products is  $86.592$  (weight)  $\times .23645$  (sp. heat)  $\times 1474^\circ$  (rise of temp.) = 30,180 heat-units: the temperature of the escaping blast gases being 1550° F., and that of the entering air 76° F. But the amount of the blast gases, by registration of an anemometer, checked by a calculation from the analyses of the blast gases, was 2457 cubic feet for every 1000 cubic feet of carburetted gas made. Hence the heat carried off per M. of carburetted gas is  $30,180 \times 2.457 = 74,152$  heat-units = *E*.

Experiments made by a radiometer covering four square feet of the shell of the apparatus gave figures for the amount of heat lost by radiation = 12,454 heat-units = *F*, and by convection = 15,696 heat-units = *G*.

The heat rendered latent by the gasification of the oil was found by taking the difference between all the heat fed into the carburetter and super-heater and the total heat dissipated therefrom to be 12,841 heat-units = *H*. The sensible heat in the ash and unconsumed coal is  $9.9$  lbs.  $\times 1500^\circ \times .25$  (sp. ht.) = 3712 heat-units = *I*.

The sum of all the items  $B + C + D + E + F + G + H + I = 327,295$  heat-units, which subtracted from the heat energy of the combustible consumed, 340,750 heat-units, leaves 13,455 heat-units, or 4 per cent, unaccounted for.

Of the total heat energy of the coal consumed, or 340,750 heat-units, the energy wasted is the sum of items *D*, *E*, *F*, *G*, and *I*, amounting to 132,878 heat-units, or 39 per cent; the remainder, or 207,872 heat-units, or 61 per cent, being utilized. The efficiency of the apparatus as a heat machine is therefore 61 per cent.

Five gallons, or 35 lbs. of crude petroleum were fed into the carburetter per 1000 cu. ft. of gas made; deducting 5 lbs. of tar recovered, leaves 30 lbs.  $\times 20,000 = 600,000$  heat-units as the net heating value of the petroleum used. Adding this to the heating value of the coal, 340,750 B. T. U., gives 940,750 heat-units, of which there is found as heat energy in the carburetted gas, as in the table below, 764,050 heat units, or 81 per cent, which is the commercial efficiency of the apparatus, i.e., the ratio of the energy contained in the finished product to the total energy of the coal and oil consumed.

The heating power per M. cu. ft. of the carburetted gas is		The heating power per M. of the uncarburetted gas is

\* The heating value of the illuminants C<sub>n</sub>H<sub>2n</sub> is assumed to equal that of C<sub>3</sub>H<sub>6</sub>.

The candle-power of the gas is 31, or 6.2 candle-power per gallon of oil used. The calculated specific gravity is .6355, air being 1.

For description of the operation of a modern carburetted water-gas plant, see paper by J. Stelfox, *Eng'g*, July 20, 1894, p. 89.

**Space required for a Water-gas Plant.**—Mr. Shelton, taking 15 modern plants of the form requiring the most floor-space, figures the average floor-space required per 1000 cubic feet of daily capacity as follows:

Water-gas Plants of Capacity in 24 hours of	Require an Area of Floor-space for each 1000 cu. ft. of about
100,000 cubic feet.....	4 square feet.
200,000 " " .....	3.5 " "
400,000 " " .....	2.75 " "
600,000 " " .....	2 to 2.5 sq. ft.
7 to 10 million cubic feet.....	1.25 to 1.5 sq. ft.

These figures include scrubbing and condensing rooms, but not boiler and engine rooms. In coal-gas plants of the most modern and compact forms one with 16 benches of 9 retorts each, with a capacity of 1,500,000 cubic feet per 24 hours, will require 4.8 sq. ft. of space per 1000 cu. ft. of gas, and one of 6 benches of 6 retorts each, with 300,000 cu. ft. capacity per 24 hours will require 6 sq. ft. of space per 1000 cu. ft. The storage-room required for the gas-making materials is: for coal-gas, 1 cubic foot of room for every 232 cubic feet of gas made; for water-gas made from coke, 1 cubic foot of room for every 373 cu. ft. of gas made; and for water-gas made from anthracite, 1 cu. ft. of room for every 645 cu. ft. of gas made.

The comparison is still more in favor of water-gas if the case is considered of a water-gas plant added as an auxiliary to an existing coal-gas plant; for, instead of requiring further space for storage of coke, part of that already required for storage of coke produced and not at once sold can be cut off, by reason of the water-gas plant creating a constant demand for more or less of the coke so produced.

Mr. Shelton gives a calculation showing that a water-gas of .625 sp. gr. would require gas-mains eight per cent greater in diameter than the same quantity coal-gas of .425 sp. gr. if the same pressure is maintained at the holder. The same quantity may be carried in pipes of the same diameter if the pressure is increased in proportion to the specific gravity. With the same pressure the increase of candle-power about balances the decrease of flow. With five feet of coal-gas, giving, say, eighteen candle-power, 1 cubic foot equals 3.6 candle-power; with water-gas of 23 candle-power, 1 cubic foot equals 4.6 candle-power, and 4 cubic feet gives 18.4 candle-power, or more than is given by 5 cubic feet of coal-gas. Water-gas may be made from oven-coke or gas-house coke as well as from anthracite coal. A water-gas plant may be conveniently run in connection with a coal-gas plant, the surplus retort coke of the latter being used as the fuel of the former.

In coal-gas making it is impracticable to enrich the gas to over twenty candle-power without causing too great a tendency to smoke, but water-gas of as high as thirty candle-power is quite common. A mixture of coal-gas and water-gas of a higher C.P. than 20 can be advantageously distributed.

**Fuel-value of Illuminating-gas.**—E. G. Love (School of Mines Q'tly, January, 1892) describes F. W. Hartley's calorimeter for determining the calorific power of gases, and gives results obtained in tests of the carburetted water-gas made by the municipal branch of the Consolidated Co. of New York. The tests were made from time to time during the past two years, and the figures give the heat-units per cubic foot at 60° F. and 30 inches pressure: 715, 692, 725, 732, 691, 738, 735, 703, 734, 730, 731, 727. Average, 721 heat units. Similar tests of mixtures of coal- and water-gases made by other branches of the same company give 694, 715, 684, 692, 727, 665, 695, and 686 heat-units per foot, or an average of 694.7. The average of all these tests was 710.5 heat-units, and this we may fairly take as representing the calorific power of the illuminating gas of New York. One thousand feet of this gas, costing \$1.25, would therefore yield 710,500 heat-units, which would be equivalent to 568,400 heat-units for \$1.00.

The common coal-gas of London, with an illuminating power of 16 to 17 candles, has a calorific power of about 668 units per foot, and costs from 60 to 70 cents per thousand.

The product obtained by decomposing steam by incandescent carbon, as effected in the Motay process, consists of about 40% of CO, and a little over 50% of H.

This mixture would have a heating-power of about 300 units per cubic foot, and if sold at 50 cents per 1000 cubic feet would furnish 600,000 units for \$1.00, as compared with 568,400 units for \$1.00 from illuminating gas at \$1.25 per 1000 cubic feet. This illuminating-gas if sold at \$1.15 per thousand would therefore be a more economical heating agent than the fuel-gas mentioned, at 50 cents per thousand, and be much more advantageous than the latter, in that one main, service, and meter could be used to furnish gas for both lighting and heating.

A large number of fuel-gases tested by Mr. Love gave from 184 to 470 heat-units per foot, with an average of 309 units.

Taking the cost of heat from illuminating-gas at the lowest figure given by Mr. Love, viz., \$1.00 for 600,000 heat-units, it is a very expensive fuel, equal to coal at \$40 per ton of 2000 lbs., the coal having a calorific power of only 12,000 heat-units per pound, or about 83% of that of pure carbon:

$$600,000 : (12,000 \times 2000) :: \$1 : \$40.$$

**FLOW OF GAS IN PIPES.**

The rate of flow of gases of different densities, the diameter of pipes required, etc., are given in King's Treatise on Coal Gas, vol. ii. 374, as follows:

$$\left. \begin{array}{l} \text{If } d = \text{diameter of pipe in inches,} \\ Q = \text{quantity of gas in cu. ft. per} \\ \text{hour,} \\ l = \text{length of pipe in yards,} \\ h = \text{pressure in inches of water,} \\ s = \text{specific gravity of gas, air being 1,} \end{array} \right\} \begin{array}{l} d = \sqrt[5]{\frac{Q^2sl}{(1350)^2h}}, \\ h = \frac{Q^2sl}{(1350)^2d^5}, \\ Q = 1350d^2 \sqrt{\frac{dh}{sl}} = 1350 \sqrt{\frac{d^5h}{sl}}. \end{array}$$

Molesworth gives  $Q = 1000 \sqrt{\frac{d^5h}{sl}}$ .

J. P. Gill, *Am. Gas-light Jour.* 1894, gives  $Q = 1291 \sqrt{\frac{d^5h}{s(l+d)}}$ .

This formula is said to be based on experimental data, and to make allowance for obstructions by tar, water, and other bodies tending to check the flow of gas through the pipe.

A set of tables in Appleton's Cyc. Mech. for flow of gas in 2, 6, and 12 in. pipes is calculated on the supposition that the quantity delivered varies as the square of the diameter instead of as  $d^2 \times \sqrt[5]{d}$ , or  $\sqrt[5]{d^5}$ .

These tables give a flow in large pipes much less than that calculated by the formulæ above given, as is shown by the following example. Length of pipe 100 yds., specific gravity of gas 0.42, pressure 1-in. water-column

	2-in. Pipe.	6-in. Pipe.	12-in. Pipe.
$Q = 1350 \sqrt{\frac{d^5h}{sl}}$ .....	1178	18,368	103,912
$Q = 1000 \sqrt{\frac{d^5h}{sl}}$ .....	873	13,606	76,972
$Q = 1291 \sqrt{\frac{d^5h}{s(l+d)}}$ .....	1116	16,327	93,845
Table in App. Cyc. ....	1290	11,657	46,628

An experiment made by Mr. Clegg, in London, with a 4-in. pipe, 6 miles long, pressure 3 in. of water, specific gravity of gas .398, gave a discharge into the atmosphere of 852 cu. ft. per hour, after a correction of 33 cu. ft. was made for leakage.

Substituting this value, 852 cu. ft., for  $Q$  in the formula  $Q = C \sqrt[5]{d^5h + sl}$ , we find  $C$ , the coefficient, = 997, which corresponds nearly with the formula given by Molesworth.

**Services for Lamps. (Molesworth.)**

Lamps.	Ft. from Main.	Require Pipe-bore.	Lamps.	Ft. from Main.	Require Pipe-bore.

Mr. A. C. Humphreys says his experience goes to show that these tables give too small a flow, but it is difficult to accurately check the tables, on account of the extra friction introduced by rough pipes, bends, etc. For bends, one rule is to allow 1/42 of an inch pressure for each right-angle bend.

Where there is apt to be trouble from frost it is well to use no service of less diameter than  $\frac{3}{4}$  in., no matter how short it may be. In extremely cold climates this is now often increased to 1 in., even for a single lamp. The best practice in the U. S. now condemns any service less than  $\frac{3}{4}$  in.

## STEAM.

**The Temperature of Steam** in contact with water depends upon the pressure under which it is generated. At the ordinary atmospheric pressure (14.7 lbs. per sq. in.) its temperature is 212° F. As the pressure is increased, as by the steam being generated in a closed vessel, its temperature, and that of the water in its presence, increases.

**Saturated Steam** is steam of the temperature due to its pressure—not superheated.

**Superheated Steam** is steam heated to a temperature above that due to its pressure.

**Dry Steam** is steam which contains no moisture. It may be either saturated or superheated.

**Wet Steam** is steam containing intermingled moisture, mist, or spray. It has the same temperature as dry saturated steam of the same pressure.

Water introduced into the presence of superheated steam will flash into vapor until the temperature of the steam is reduced to that due its pressure. Water in the presence of saturated steam has the same temperature as the steam. Should cold water be introduced, lowering the temperature of the whole mass, some of the steam will be condensed, reducing the pressure and temperature of the remainder, until an equilibrium is established.

**Temperature and Pressure of Saturated Steam.**—The relation between the temperature and the pressure of steam, according to Regnault's experiments, is expressed by the formula (Buchanan's, as given

by Clark)  $t = \frac{2938.16}{6.1993544 - \log p} - 371.85$ , in which  $p$  is the pressure in pounds

per square inch and  $t$  the temperature of the steam in Fahrenheit degrees. It applies with accuracy between 120° F. and 446° F., corresponding to pressures of from 1.68 lbs. to 445 lbs. per square inch. (For other formulæ see Wood's and Peabody's Thermodynamics.)

**Total Heat of Saturated Steam** (above 32° F.).—According to Regnault's experiments, the formula for total heat of steam is  $H = 1091.7 + .305(t - 32^\circ)$ , in which  $t$  is temperature Fahr., and  $H$  the heat-units. (Rankine and many others; Clark gives 1091.16 instead of 1091.7.)

**Latent Heat of Steam.**—The formula for latent heat of steam, as given by Rankine and others, is  $L = 1091.7 - .695(t - 32^\circ)$ . Clausius's formula, in Fahrenheit units, as given by Clark, is  $L = 1092.6 - .708(t - 32^\circ)$ .

The total heat in steam (above 32°) includes three elements:

- 1st. The heat required to raise the temperature of the water to the temperature of the steam.
- 2d. The heat required to evaporate the water at that temperature, called internal latent heat.
- 3d. The latent heat of volume, or the external work done by the steam in making room for itself against the pressure of the superincumbent atmosphere (or surrounding steam if inclosed in a vessel).

The sum of the last two elements is called the latent heat of steam. In Buel's tables (Weisbach, vol. ii., Dubois's translation) the two elements are given separately.

**Latent Heat of Volume of Saturated Steam.** (External Work.)—The following formulas are sufficiently accurate for occasional use within the given ranges of pressure (Clark, S. E.):

- From 14.7 lbs. to 50 lbs. total pressure per square inch... 55.900 + .0772*t*.
- From 50 lbs. to 200 lbs. total pressure per square inch.... 59.191 + .0655*t*.

**Heat required to Generate 1 lb. of Steam** from water at 32° F.

	Heat-units.
Sensible heat, to raise the water from 32° to 212° = ....	180.9
Latent heat, 1, of the formation of steam at 212° = ....	894.0
2, of expansion against the atmospheric pressure, 2116.4 lbs. per sq. ft. × 26.36 cu. ft. = 55,786 foot-pounds ÷ 778 = .....	71.7    965.7
Total heat above 32° F.....	1146.6

**The Heat Unit, or British Thermal Unit.**—The definition of the heat-unit used in this work is that of Rankine, accepted by most modern writers, viz., the quantity of heat required to raise the temperature of 1 lb. of water 1° F. at or near its temperature of maximum density (39.1° F.). Peabody's definition, the heat required to raise a pound of water from 62° to 63° F. is not generally accepted. (See Thurston, Trans. A. S. M. E., xiii. 351.)

**Specific Heat of Saturated Steam.**—The specific heat of saturated steam is .305, that of water being 1; or it is 1.281, if that of air be 1. The expression .305 for specific heat is taken in a compound sense, relating to changes both of volume and of pressure which takes place in the elevation of temperature of saturated steam. (Clark, S. E.)

This statement by Clark is not strictly accurate. When the temperature of saturated steam is elevated, water being present and the steam remaining saturated, water is evaporated. To raise the temperature of 1 lb. of water 1° F. requires 1 thermal unit, and to evaporate it at 1° F. higher would require 0.695 less thermal unit, the latent heat of saturated steam decreasing 0.695 B.T.U. for each increase of temperature of 1° F. Hence 0.305 is the specific heat of water and its saturated vapor combined.

When a unit weight of saturated steam is increased in temperature and in pressure, the volume decreasing so as to just keep it saturated, the specific heat is negative, and decreases as temperature increases. (See Wood, Therm., p. 147; Peabody, Therm., p. 93.)

**Density and Volume of Saturated Steam.**—The density of steam is expressed by the weight of a given volume, say one cubic foot; and the volume is expressed by the number of cubic feet in one pound of steam.

Mr. Brownlee's expression for the density of saturated steam in terms of the pressure is  $D = \frac{p^{.941}}{330.36}$ , or  $\log D = .941 \log p - 2.519$ , in which *D* is the density, and *p* the pressure in pounds per square inch. In this expression,  $p^{.941}$  is the equivalent of *p* raised to the 16/17 power, as employed by Rankine.

The volume *v* being the reciprocal of the density,

$$v = \frac{330.36}{p^{.941}}, \text{ or } \log v = 2.519 - .941 \log p.$$

**Relative Volume of Steam.**—The relative volume of saturated steam is expressed by the number of volumes of steam produced from one

volume of water, the volume of water being measured at the temperature 39° F. The relative volume is found by multiplying the volume in cu. ft. of one lb. of steam by the weight of a cu. ft. of water at 39° F., or 62.425 lbs.

**Gaseous Steam.**—When saturated steam is superheated, or surcharged with heat, it advances from the condition of saturation into that of gaseity. The gaseous state is only arrived at by considerably elevating the temperature, supposing the pressure remains the same. Steam thus sufficiently superheated is known as gaseous steam or steam gas.

**Total Heat of Gaseous Steam.**—Regnault found that the total heat of gaseous steam increased, like that of saturated steam, uniformly with the temperature, and at the rate of .475 thermal units per pound for each degree of temperature, under a constant pressure.

The general formula for the total heat of gaseous steam produced from 1 pound of water at 32° F. is  $H = 1074.6 + .475t$ . [This formula is for vapor generated at 32°. It is not true if generated at 212°, or at any other temperature than 32°. (Prof. Wood)]

**The Specific Heat of Gaseous Steam** is .475, under constant pressure, as found by Regnault. It is identical with the coefficient of increase of total heat for each degree of temperature. [This is at atmospheric pressure and 212° F. He found it not true for any other pressure. Theory indicates that it would be greater at higher temperatures. (Prof. Wood)]

**The Specific Density of Gaseous Steam** is .622, that of air being 1. That is to say, the weight of a cubic foot of gaseous steam is about five eighths of that of a cubic foot of air, of the same pressure and temperature.

The density or weight of a cubic foot of gaseous steam is expressible by the same formula as that of air, except that the multiplier or coefficient is less in proportion to the less specific density. Thus,

$$D' = \frac{2.7074p \times .622}{t + 461} = \frac{1.684p}{t + 461}$$

in which  $D'$  is the weight of a cubic foot of gaseous steam,  $p$  the total pressure per square inch, and  $t$  the temperature Fahrenheit.

**Superheated Steam.**—The above remarks concerning gaseous steam are taken from Clark's Steam engine. Wood gives for the total heat (above 32°) of superheated steam  $H = 1091.7 + 0.48(t - 32°)$ .

The following is abridged from Peabody (Therm., p. 115, etc.).

When far removed from the temperature of saturation, superheated steam follows the laws of perfect gases very nearly, but near the temperature of saturation the departure from those laws is too great to allow of calculations by them for engineering purposes.

The specific heat at constant pressure,  $C_p$ , from the mean of three experiments by Regnault, is 0.4805.

Values of the ratio of  $C_p$  to specific heat at constant volume:

Pressure $p$ , pounds per square inch..	5	50	100	200	300
Ratio $C_p \div C_v = k =$	1.335	1.332	1.330	1.324	1.316

Zeuner takes  $k$  as a constant = 1.333.

SPECIFIC HEAT AT CONSTANT VOLUME, SUPERHEATED STEAM.

Pressure, pounds per square inch.....	5	50	100	200	300
Specific heat $C_v$ .....	0.351	.348	.346	.344	.341

It is quite as reasonable to assume that  $C_v$  is a constant as to suppose that  $C_p$  is constant, as has been assumed. If we take  $C_v$  to be constant, then  $C_p$  will appear as a variable.

If  $p$  = pressure in lbs. per sq. ft.,  $v$  = volume in cubic feet, and  $T$  = temperature in degrees Fahrenheit + 460.7, then  $pv = 93.5T - 971p^{\frac{1}{4}}$ .

Total heat of superheated steam,  $H = 0.4805(T - 10.38p^{\frac{1}{4}}) + 857.2$ .

**The Rationalization of Regnault's Experiments on Steam.** (J. McFarlane Gray, Proc. Inst. M. E., July, 1889.)—The formulæ constructed by Regnault are strictly empirical, and were based entirely on his experiments. They are therefore not valid beyond the range of temperatures and pressures observed.

Mr. Gray has made a most elaborate calculation, based not on experiments but on fundamental principles of thermodynamics, from which he deduces formulæ for the pressure and total heat of steam, and presents tables calcu-

lated therefrom which show substantial agreement with Regnault's figures. He gives the following examples of steam-pressures calculated for temperatures beyond the range of Regnault's experiments.

Temperature.		Pounds per sq. in.	Temperature.		Pounds per sq. in.
C.	Fahr.		C.	Fahr.	
230	446	406.9	310	644	2156.2
240	464	488.9	360	680	2742.5
250	482	579.9	380	716	3448.1
260	500	691.6	400	752	4300.2
280	536	940.0	415	779	5017.1
300	572	1261.8	427	800.6	5659.9
320	608	1661.9			

These pressures are higher than those obtained by Regnault's formula, which gives for 415° C. only 4067.1 lbs. per square inch.

**Table of the Properties of Saturated Steam.**—In the table of properties of saturated steam on the following pages the figures for temperature, total heat, and latent heat are taken, up to 210 lbs. absolute pressure, from the tables in Porter's Steam-engine Indicator, which tables have been widely accepted as standard by American engineers. The figures for total heat, given in the original as from 0° F., have been changed to heat above 32° F. The figures for weight per cubic foot and for cubic feet per pound have been taken from Dwelshauvers-Dery's table, Trans. A. S. M. E., vol. xi., as being probably more accurate than those of Porter. The figures for relative volume are from Buel's table, in Dubois's translation of Weisbach, vol. ii. They agree quite closely with the relative volumes calculated from weights as given by Dwelshauvers. From 211 to 219 lbs. the figures for temperature, total heat, and latent heat are from Dwelshauvers' table; and from 220 to 1000 lbs. all the figures are from Buel's table. The figures have not been carried out to as many decimal places as they are in most of the tables given by the different authorities; but any figure beyond the fourth significant figure is unnecessary in practice, and beyond the limit of error of the observations and of the formulæ from which the figures were derived.

### Weight of 1 Cubic Foot of Steam in Decimals of a Pound. Comparison of Different Authorities.

80	.19015	.1863	.1866	.1862	.1843	220	.....	.4842	.4852	.....	.4772
100	.23302	.2307	.2303	.2296	.2271	240	.....	.5248	.5270	.....	.5186

There are considerable differences between the figures of weight and volume of steam as given by different authorities. Porter's figures are based on the experiments of Fairbairn and Tate. The figures given by the other authorities are derived from theoretical formulæ which are believed to give more reliable results than the experiments. The figures for temperature, total heat, and latent heat as given by different authorities show a practical agreement, all being derived from Regnault's experiments. See Peabody's Tables of Saturated Steam; also Jacobus, Trans. A. S. M. E., vol. xii., 593.

**FLOW OF STEAM.**

**Flow of Steam through a Nozzle.** (From Clark on the Steam-engine.)—The flow of steam of a greater pressure into an atmosphere of a less pressure increases as the difference of pressure is increased, until the external pressure becomes only 58% of the absolute pressure in the boiler. The flow of steam is neither increased nor diminished by the fall of the external pressure below 58%, or about 4/7ths of the inside pressure, even to the extent of a perfect vacuum. In flowing through a nozzle of the best form, the steam expands to the external pressure, and to the volume due to this pressure, so long as it is not less than 58% of the internal pressure. For an external pressure of 58%, and for lower percentages, the ratio of expansion is 1 to 1.624. The following table is selected from Mr. Brownlee's data exemplifying the rates of discharge under a constant internal pressure, into various external pressures:

**Outflow of Steam; from a Given Initial Pressure into Various Lower Pressures.**

Absolute initial pressure in boiler, 75 lbs. per sq. in.

Absolute Pressure in Boiler per square inch.	External Pressure per square inch.	Ratio of Expansion in Nozzle.	Velocity of Outflow at Constant Density.	Actual Velocity of Outflow Expanded.	Discharge per square inch of Orifice per minute.

	{ 58 p. cent }				
75	15	1.624	890.6	1446.5	65.3
75	0	1.624	890.6	1446.5	65.3

When steam of varying initial pressures is discharged into the atmosphere—the atmospheric pressure being not more than 58% of the initial pressure—the velocity of outflow at constant density, that is, supposing the initial density to be maintained, is given by the formula  $V = 3.5953 \sqrt{h}$ .

$V$  = the velocity of outflow in feet per second, as for steam of the initial density;

$h$  = the height in feet of a column of steam of the given absolute initial pressure of uniform density, the weight of which is equal to the pressure on the unit of base.

The lowest initial pressure to which the formula applies, when the steam is discharged into the atmosphere at 14.7 lbs. per square inch, is  $(14.7 \times 100/58 =)$  25.37 lbs. per square inch. Examples of the application of the formula are given in the table below.

From the contents of this table it appears that the velocity of outflow into the atmosphere, of steam above 25 lbs. per square inch absolute pressure, or 10 lbs. effective, increases very slowly with the pressure, obviously because the density, and the weight to be moved, increase with the pressure. An average of 900 feet per second may, for approximate calculations, be taken for the velocity of outflow as for constant density, that is, taking the volume of the steam at the initial volume.

**Outflow of Steam into the Atmosphere.**—External pressure per square inch 14.7 lbs. absolute. Ratio of expansion in nozzle, 1.624.

Absolute Initial Pressure per square inch.	Velocity of Outflow as at Constant Density.	Actual Velocity of Outflow Expanded.	Discharge per square inch of Orifice per min.	Horse-power per sq. in. of Orifice if H. P. = 30 lbs. per hour.	Absolute Initial Pressure per square inch.	Velocity of Outflow as at Constant Density.	Actual Velocity of Outflow Expanded. **Napier's Approximate Rule.**—Flow in pounds per second = absolute pressure  $\times$  area in square inches  $\div$  70. This rule gives results which closely correspond with those in the above table, as shown below.

Abs. press., lbs. p. sq. in.	25.37	40	60	75	100	135	165	215
Discharge per min., by table, lbs. ....	22.81	35.18	52.59	65.30	86.34	115.61	140.46	181.58
By Napier's rule. ....	21.74	34.29	51.43	64.29	85.71	115.71	141.43	184.29

Prof. Peabody, in Trans. A. S. M. E., xi, 187, reports a series of experiments on flow of steam through tubes  $\frac{1}{4}$  inch in diameter, and  $\frac{1}{4}$ ,  $\frac{1}{2}$ , and  $1\frac{1}{2}$  inch long, with rounded entrances, in which the results agreed closely with Napier's formula, the greatest difference being an excess of the experimental over the calculated result of 3.2%. An equation derived from the theory of thermodynamics is given by Prof. Peabody, but it does not agree with the experimental results as well as Napier's rule, the excess of the actual flow being 6.6%.

**Flow of Steam in Pipes.**—A formula commonly used for velocity of flow of steam in pipes is the same as Downing's for the flow of water in smooth cast-iron pipes, viz.,  $V = 50 \sqrt{\frac{H}{L}} D$ , in which  $V$  = velocity in feet per second,  $L$  = length and  $D$  = diameter of pipe in feet,  $H$  = height in feet of a column of steam, of the pressure of the steam at the entrance,

which would produce a pressure equal to the difference of pressures at the two ends of the pipe. (For derivation of the coefficient 50, see Briggs on "Warming Buildings by Steam," Proc. Inst. C. E. 1882.)

If  $Q$  = quantity in cubic feet per minute,  $d$  = diameter in inches,  $L$  and  $H$  being in feet, the formula reduces to

$$Q = 4.7233 \sqrt{\frac{H}{L}} d^5, \quad H = .0448 \frac{Q^2 L}{d^5}, \quad d = .5374 \sqrt[5]{\frac{Q^2 L}{H}}.$$

(These formulæ are applicable to air and other gases as well as steam.)

If  $p_1$  = pressure in pounds per square inch of the steam (or gas) at the entrance to the pipe,  $p_2$  = the pressure at the exit, then  $144(p_1 - p_2)$  = difference in pressure per square foot. Let  $w$  = density or weight per cubic foot of steam at the pressure  $p_1$ , then the height of column equivalent to the difference in pressures

$$= H = \frac{144(p_1 - p_2)}{w}, \quad \text{and} \quad Q = 60 \times .7854 \times 50 D^2 \sqrt{\frac{144(p_1 - p_2) D}{w L}}.$$

If  $W$  = weight of steam flowing in pounds per minute =  $Qw$ , and  $d$  is taken in inches,  $L$  being in feet,

$$W = 56.68 \sqrt{\frac{w(p_1 - p_2)d^5}{L}}; \quad Q = 56.68 \sqrt{\frac{(p_1 - p_2)d^5}{Lw}};$$

$$d = 0.199 \sqrt[5]{\frac{W^2 L}{w(p_1 - p_2)}} = 0.199 \sqrt[5]{\frac{Q^2 w L}{p_1 - p_2}}.$$

$$\text{Velocity in feet per minute} = V = Q \div .7854 \frac{d^2}{144} = 10392 \sqrt{\frac{(p_1 - p_2)d}{w L}}.$$

$$\text{For a velocity of 6000 feet per minute, } d = \frac{w L}{3(p_1 - p_2)}; \quad p_1 - p_2 = \frac{w L}{3d}.$$

For a velocity of 6000 feet per minute, a steam-pressure of 100 lbs. gauge, or  $w = .264$ , and a length of 100 feet,  $d = \frac{8.8}{p_1 - p_2}$ ;  $p_1 - p_2 = \frac{8.8}{d}$ . That is, a pipe 1 inch diameter, 100 feet long, carrying steam of 100 lbs. gauge-pressure at 6000 feet velocity per minute, would have a loss of pressure of 8.8 lbs. per square inch, while steam travelling at the same velocity in a pipe 8.8 inches diameter would lose only 1 lb. pressure.

G. H. Babcock, in "Steam," gives the formula

$$W = 87 \sqrt{\frac{w(p_1 - p_2)d^5}{L \left(1 + \frac{3.6}{d}\right)}}.$$

In earlier editions of "Steam" the coefficient is given as 300,—evidently an error,—and this value has been reprinted in Clark's Pocket-Book (1892 edition). It is apparently derived from one of the numerous formulæ for flow of water in pipes, the multiplier of  $L$  in the denominator being used for an expression of the increased resistance of small pipes. Putting this formula

in the form  $W = c \sqrt{\frac{w(p_1 - p_2)d^5}{L}}$ , in which  $c$  will vary with the diameter

of the pipe, we have,

For diameter, inches....	1	2	3	4	6	9	12
Value of $c$ .....	40.7	52.1	58.8	63	68.8	73.7	79.3

instead of the constant value 56.68, given with the simpler formula.

One of the most widely accepted formulæ for flow of water is D'Arcy's,

$$V = c \sqrt{\frac{HD}{L}}, \quad \text{in which } c \text{ has values ranging from 65 for a } \frac{1}{2}\text{-inch pipe up to}$$

111.5 for 24-inch. Using D'Arcy's coefficients, and modifying his formula to make it apply to steam, to the form

$$Q = c \sqrt{\frac{(p_1 - p_2)d^5}{wL}}, \text{ or } W = c \sqrt{\frac{w(p_1 - p_2)d^5}{L}},$$

we obtain,

For diameter, inches....	1/2	1	2	3	4	5	6	7	8
Value of c.....	36.8	45.3	52.7	56.1	57.8	58.4	59.5	60.1	60.7
For diameter, inches....	9	10	12	14	16	18	20	22	24
Value of c.....	61.2	61.8	62.1	62.3	62.6	62.7	62.9	63.2	63.2

In the absence of direct experiments these coefficients are probably as accurate as any that may be derived from formulæ for flow of water.

$$\text{Loss of pressure in lbs. per sq. in.} = p_1 - p_2 = \frac{Q^2 w L}{c^2 d^5} = \frac{W^2 L}{c^2 w d^5}.$$

**Loss of Pressure due to Radiation as well as Friction.**— E. A. Rudiger (*Mechanics*, June 30, 1883) gives the following formulæ and tables for flow of steam in pipes. He takes into consideration the losses in pressure due both to radiation and to friction.

$$\text{Loss of power, expressed in heat-units due to friction, } H_f = \frac{W^3 f l}{10 p^2 d^5}.$$

$$\text{Loss due to radiation, } H_r = 0.262 r l d.$$

In which  $W$  is the weight in lbs. of steam delivered per hour,  $f$  the coefficient of friction of the pipe,  $l$  the length of the pipe in feet,  $p$  the absolute terminal pressure,  $d$  the diameter of the pipe in inches, and  $r$  the coefficient of radiation.  $f$  is taken as from .0165 to .0175, and  $r$  varies as follows:

TABLE OF VALUES FOR  $r$ .

Pipe Covering.	Absolute Pressure.			
	40 lbs.	65 lbs.	90 lbs.	115 lbs.
Uncovered pipe.....	437	555	620	684
2-inch cement composition.....	146	178	193	209
2 " asbestos.....	157	192	202	222
2 " asbestos flock.....	150	185	197	210
2 " wooden log.....	100	122	145	151
2 " mineral wool.....	61	76	85	93
2 " hair felt.....	48	58	66	73

The appended table shows the loss due to friction and radiation in a steam-pipe where the quantity of steam to be delivered is 1000 lbs. per hour,  $l = 1000$  feet, the pipe being so protected that loss by radiation  $r = 64$ , and the absolute terminal pressure being 90 lbs.:

Diameter of Pipe, inches.	Loss by Friction, $H_f$ .	Loss by Radiation, $H_r$ .	Total Loss, $L$ .	Diam. of Pipe, inches.	Loss by Friction, $H_f$ .	Loss by Radiation, $H_r$ .	Total Loss, $L$ .
1	197,531	16,768	214,300	3 1/2	376	58,688	59,064
1 1/4	64,727	20,960	85,687	4	193	67,072	67,265
1 1/2	26,012	25,152	51,164	5	63	83,840	83,903
1 3/4	12,035	29,344	41,379	6	25	100,608	100,633
2	6,173	33,536	39,709	7	12	117,376	117,388
2 1/2	2,023	41,920	43,943	8	6	134,144	134,150
3	813	50,304	51,117				

If the pipes are carrying steam with minimum loss, then for same  $r$ ,  $l$ , and  $p$ , the loss of pressure  $L$  for pipes of different diameters varies inversely as the diameters.

The general equation for the loss of pressure for the minimal loss from friction and radiation is

$$L = \frac{0.0007023 \text{ } d r l p}{W}$$

The loss of pressure for pipes of 1 inch diameter for different absolute terminal pressures when steam is flowing with minimal loss is expressed by the formula  $L = C l \sqrt[3]{r^2}$ , in which the coefficient  $C$  has the following values:

For 65 lbs. abs. term. pressure.....	$C = 0.00089337$
“ 75 “ “ “ “ .....	0.00093684
“ 90 “ “ “ “ .....	0.00099573
“ 100 “ “ “ “ .....	0.00103132
“ 115 “ “ “ “ .....	0.00108051

In order to find the loss of pressure for any other diameter, divide the loss of pressure in a 1-inch pipe for the given terminal pressure by the given diameter, and the quotient will be the loss of pressure for that diameter.

The following is a general summary of the results of Mr. Rudiger's investigation :

The flow of steam in a pipe is determined in the same manner as the flow of water, the formula for the flow of steam being modified only by substituting the equivalent loss of pressure, divided by the density of the steam, for the loss of head.

The losses in the flow of steam are two in number—the loss due to the friction of flow and that due to radiation from the sides of the pipe. The sum of these is a minimum when the equivalent of the loss due to friction of flow is equal to one fifth of the loss of heat by radiation. For a greater or less loss of pressure—i.e., for a less or greater diameter of pipe—the total loss increases very rapidly.

For delivering a given quantity of steam at a given terminal pressure, with minimal total loss, the better the non-conducting material employed, the larger the diameter of the steam-pipe to be used.

The most economical loss of pressure for a pipe of given diameter is equal to the most economical loss of pressure in a pipe of 1 inch diameter for same conditions, divided by the diameter of the given pipe in inches.

The following table gives the capacity of pipes of different diameters, to deliver steam at different terminal pressures through a pipe one half mile long for loss of pressure of 10 lbs., and a mean value of  $f = 0.0175$ . Let  $W$  denote the number of pounds of steam delivered per hour :

Diameter of Pipe, inches.	Abs. Term. Pressure.			Diameter of Pipe, inches.	Abs. Term. Pressure.

**Resistance to Flow by Bends, Valves, etc.** (From Briggs on Warming Buildings by Steam.)—The resistance at the entrance to a tube when no special bell-mouth is given consists of two parts. The head  $v^2 \div 2g$  is expended in giving the velocity of flow; and the head  $0.505 \frac{v^2}{2g}$  in over-

coming the resistance of the mouth of the tube. Hence the whole loss of head at the entrance is  $1.505 \frac{v^2}{2g}$ . This resistance is equal to the resistance of a straight tube of a length equal to about 60 times its diameter.

The loss at each sharp right-angled elbow is the same as in flowing through a length of straight tube equal to about 40 times its diameter. For a globe steam stop-valve the resistance is taken to be  $1\frac{1}{2}$  times that of the right-angled elbow.

**Sizes of Steam-pipes for Stationary Engines.**—Authorities on the steam-engine generally agree that steam-pipes supplying engines should be of such size that the mean velocity of steam in them does not exceed 6000 feet per minute, in order that the loss of pressure due to friction may not be excessive. The velocity is calculated on the assumption that the cylinder is filled at each stroke. In very long pipes, 100 feet and upward, it is well to make them larger than this rule would give, and to place a large steam receiver on the pipe near the engine, especially when the engine cuts off early in the stroke.

An article in *Power*, May, 1893, on proper area of supply-pipes for engines gives a table showing the practice of leading builders. To facilitate comparison, all the engines have been rated in horse-power at 40 pounds mean effective pressure. The table contains all the varieties of simple engines, from the slide-valve to the Corliss, and it appears that there is no general difference in the sizes of pipe used in the different types.

The averages selected from this table are as follows:

Diam. of pipe, in. ....	2	2½	3	3½	4	4½	5	6	7	8	9	10
Av. H.P. of engines ....	25	39	56	77	100	126	156	225	306	400	506	625
Calculated, formula (1)	23	36	51	70	91	116	143	206	278	366	463	571
“ formula (2)	24	37.5	54	73	96	121	150	216	294	384	486	600

Formula (1) is: 1 H.P. requires .1375 sq. in. of steam-pipe area.

Formula (2) is: Horse-power =  $6d^2$ .  $d$  = diam. of pipe in inches.

The factor .1375 in formula (1) is thus derived: Assume that the linear velocity of steam in the pipe should not exceed 6000 feet per minute, then pipe area = cyl. area × piston-speed ÷ 6000 ( $a$ ). Assume that the av. mean effective pressure is 40 lbs. per sq. in., then cyl. area × piston-speed × 40 ÷ 33,000 = horse-power ( $b$ ). Dividing ( $a$ ) by ( $b$ ) and cancelling, we have pipe area ÷ H.P. = .1375 sq. in. If we use 8000 ft. per min. as the allowable velocity, then the factor .1375 becomes .1031; that is, pipe area ÷ H.P. = .1031, or pipe area × 9.7 = horse-power. This, however, gives areas of pipe smaller than are used in the most recent practice. A formula which gives results closely agreeing with practice, as shown in the above table is

$$\text{Horse-power} = 6d^2, \text{ or pipe diameter} = \sqrt{\frac{\text{H.P.}}{6}} = .408 \sqrt{\text{H.P.}}$$

DIAMETERS OF CYLINDERS CORRESPONDING TO VARIOUS SIZES OF STEAM-PIPES BASED ON PISTON-SPEED OF ENGINE OF 600 FT. PER MINUTE, AND ALLOWABLE MEAN VELOCITY OF STEAM IN PIPE OF 4000, 6000, AND 8000 FT. PER MIN. (STEAM ASSUMED TO BE ADMITTED DURING FULL STROKE.)

Diam. of pipe, inches.....	2	2½	3	3½	4	4½	5	6
Vel. 4000.. .....	5.2	6.5	7.7	9.0	10.3	11.6	12.9	15.5

“ 8000. ....	7.3	9.1	10.9	12.8	14.6	16.4	18.3	21.9
Horse-power, approx.....	20	31	45	62	80	100	125	180
Diam. of pipe, inches.....	7	8	9	10	11	12	13	14
Vel. 4000. ....	18.1	20.7	23.2	25.8	28.4	31.0	33.6	36.1
“ 6000.....	22.1	25.3	28.5	31.6	34.8	37.9	41.1	44.3
“ 8000.....	25.6	29.2	32.9	36.5	40.2	43.8	47.5	51.1
Horse-power, approx.....	245	320	406	500	606	718	845	981

$$\text{Formula. Area of pipe} = \frac{\text{Area of cylinder} \times \text{piston-speed}}{\text{mean velocity of steam in pipe}}$$

For piston-speed of 600 ft. per min. and velocity in pipe of 4000, 6000, and 8000 ft. per min. area of pipe = respectively .15, .10, and .075 × area of cylinder. Diam. of pipe = respectively .3873, .3162, and .2739 × diam. of cylinder. Reciprocals of these figures are 2.582, 3.162, and 3.651.

The first line in the above table may be used for proportioning exhaust

pipes, in which a velocity not exceeding 4000 ft. per minute is advisable. The last line, approx. H.P. of engine, is based on the velocity of 6000 ft. per min. in the pipe, using the corresponding diameter of piston, and taking  $H.P. = \frac{1}{2}(\text{diam. of piston in inches})^2$ .

**Sizes of Steam-pipes for Marine Engines.**—In marine-engine practice the steam-pipes are generally not as large as in stationary practice for the same sizes of cylinder. Seaton gives the following rules:

*Main Steam-pipes* should be of such size that the mean velocity of flow does not exceed 8000 ft. per min.

In large engines, 1000 to 2000 H.P., cutting off at less than half stroke, the steam-pipe may be designed for a mean velocity of 9000 ft., and 10,000 ft. for still larger engines.

In small engines and engines cutting later than half stroke, a velocity of less than 8000 ft. per minute is desirable.

Taking 8100 ft. per min. as the mean velocity,  $S$  speed of piston in feet per min., and  $D$  the diameter of the cyl.,

$$\text{Diam. of main steam-pipe} = \sqrt{\frac{D^2 S}{8100}} = \frac{D}{90} \sqrt{S}.$$

*Stop and Throttle Valves* should have a greater area of passages than the area of the main steam-pipe, on account of the friction through the circuitous passages. The shape of the passages should be designed so as to avoid abrupt changes of direction and of velocity of flow as far as possible.

*Area of Steam Ports and Passages* =

$$\frac{\text{Area of piston} \times \text{speed of piston in ft. per min.}}{6000} = \frac{(\text{Diam.})^2 \times \text{speed}}{7639}.$$

*Opening of Port to Steam.*—To avoid wire-drawing during admission the area of opening to steam should be such that the mean velocity of flow does not exceed 10,000 ft. per min. To avoid excessive clearance the width of port should be as short as possible, the necessary area being obtained by length (measured at right angles to the line of travel of the valve). In practice this length is usually 0.6 to 0.8 of the diameter of the cylinder, but in long-stroke engines it may equal or even exceed the diameter.

*Exhaust Passages and Pipes.*—The area should be such that the mean velocity of the steam should not exceed 6000 ft. per min., and the area should be greater if the length of the exhaust-pipe is comparatively long. The area of passages from cylinders to receivers should be such that the velocity will not exceed 5000 ft. per min.

The following table is computed on the basis of a mean velocity of flow of 8000 ft. per min. for the main steam-pipe, 10,000 for opening to steam, and 6000 for exhaust.  $A$  = area of piston,  $D$  its diameter.

STEAM AND EXHAUST OPENINGS.

### STEAM PIPES.

**Bursting-tests of Copper Steam-pipes.** (From Report of Chief Engineer Melville, U. S. N., for 1892.)—Some tests were made at the New York Navy Yard which show the unreliability of brazed seams in copper pipes. Each pipe was 8 in. diameter inside and 3 ft.  $1\frac{5}{8}$  in. long. Both ends were closed by ribbed heads and the pipe was subjected to a hot-water pressure, the temperature being maintained constant at  $371^\circ \text{F}$ . Three

of the pipes were made of No. 4 sheet copper ("Stubbs" gauge) and the fourth was made of No. 3 sheet.

The following were the results, in lbs. per sq. in., of bursting-pressure:

Pipe number.....	1	2	3	4	4'
Actual bursting-strength.....	835	785	950	1225	1275
Calculated " ".....	1336	1336	1569	1568	1568
Difference.....	501	551	619	343	293

The theoretical bursting-pressure of the pipes was calculated by using the figures obtained in the tests for the strength of copper sheet with a brazed joint at 350° F. Pipes 1 and 2 are considered as having been annealed.

The tests of specimens cut from the ruptured pipes show the injurious action of heat upon copper sheets; and that, while a white heat does not change the character of the metal, a heat of only slightly greater degree causes it to lose the fibrous nature that it has acquired in rolling, and a serious reduction in its tensile strength and ductility results.

All the brazing was done by expert workmen, and their failure to make a pipe-joint without burning the metal at some point makes it probable that, with copper of this or greater thickness, it is seldom accomplished.

That it is possible to make a joint without thus injuring the metal was proven in the cases of many of the specimens, both of those cut from the pipes and those made separately, which broke with a fibrous fracture.

**Rule for Thickness of Copper Steam-pipes.** (U. S. Super-vising Inspectors of Steam Vessels.)—Multiply the working steam-pressure in lbs. per sq. in. allowed the boiler by the diameter of the pipe in inches, then divide the product by the constant whole number 8000, and add .0625 to the quotient; the sum will give the thickness of material required.

**EXAMPLE.**—Let 175 lbs. = working steam-pressure per sq. in. allowed the boiler, 5 in. = diameter of the pipe; then  $\frac{175 \times 5}{8000} + .0625 = .1718 +$  inch, thickness required.

**Reinforcing Steam-pipes.** (*Eng.*, Aug. 11, 1893.)—In the Italian Navy copper pipes above 8 in. diam. are reinforced by wrapping them with a close spiral of copper or Delta-metal wire. Two or three independent spirals are used for safety in case one wire breaks. They are wound at a tension of about  $1\frac{1}{2}$  tons per sq. in.

**Wire-wound Steam-pipes.**—The system instituted by the British Admiralty of winding all steam-pipes over 8 in. in diameter with  $\frac{3}{16}$ -in. copper wire, thereby about doubling the bursting-pressure, has within recent years been adopted on many merchant steamers using high-pressure steam, says the *London Engineer*. The results of some of the Admiralty tests showed that a wire pipe stood just about the pressure it ought to have stood when unwired, had the copper not been injured in the brazing.

**Riveted Steel Steam-pipes** have recently been used for high pressures. See paper on A Method of Manufacture of Large Steam-pipes, by Chas. H. Manning, *Trans. A. S. M. E.*, vol. xv.

**Valves in Steam-pipes.**—Should a globe-valve on a steam-pipe have the steam-pressure on top or underneath the valve is a disputed question. With the steam-pressure on top, the stuffing-box around the valve-stem cannot be repacked without shutting off steam from the whole line of pipe; on the other hand, if the steam-pressure is on the bottom of the valve it all has to be sustained by the screw-thread on the valve-stem, and there is danger of stripping the thread.

A correspondent of the *American Machinist*, 1892, says that it is a very uncommon thing in the ordinary globe-valve to have the thread give out, but by water-hammer and merciless screwing the seat will be crushed down quite frequently. Therefore with plants where only one boiler is used he advises placing the valve with the boiler-pressure underneath it. On plants where several boilers are connected to one main steam-pipe he would reverse the position of the valve, then when one of the valves needs repacking the valve can be closed and the pressure in the boiler whose pipe it controls can be reduced to atmospheric by lifting the safety-valve. The repacking can then be done without interfering with the operation of the other boilers of the plant.

He proposes also the following other rules for locating valves: Place valves with the stems horizontal to avoid the formation of a water-pocket. Never put the junction-valve close to the boiler if the main pipe is above the boiler, but put it on the highest point of the junction-pipe. If the other

plan is followed, the pipe fills with water whenever this boiler is stopped and the others are running, and breakage of the pipe may cause serious results. Never let a junction-pipe run into the bottom of the main pipe, but into the side or top. Always use an angle-valve where convenient, as there is more room in them. Never use a gate valve under high pressure unless a by-pass is used with it. Never open a blow-off valve on a boiler a little and then shut it; it is sure to catch the sediment and ruin the valve; throw it well open before closing. Never use a globe-valve on an indicator-pipe. For water, always use gate or angle valves or stop-cocks to obtain a clear passage. Buy if possible valves with renewable disks. Lastly, never let a man go inside a boiler to work, especially if he is to hammer on it, unless you break the joint between the boiler and the valve and put a plate of steel between the flanges.

**A Failure of a Brazed Copper Steam-pipe** on the British steamer *Prodano* was investigated by Prof. J. O. Arnold. He found that the brazing was originally sound, but that it had deteriorated by oxidation of the zinc in the brazing alloy by electrolysis, which was due to the presence of fatty acids produced by decomposition of the oil used in the engines. A full account of the investigation is given in *The Engineer*, April 15, 1898.

**The "Steam Loop"** is a system of piping by which water of condensation in steam-pipes is automatically returned to the boiler. In its simplest form it consists of three pipes, which are called the riser, the horizontal, and the drop-leg. When the steam-loop is used for returning to the boiler the water of condensation and entrainment from the steam-pipe through which the steam flows to the cylinder of an engine, the riser is generally attached to a separator; this riser empties at a suitable height into the horizontal, and from thence the water of condensation is led into the drop-leg, which is connected to the boiler, into which the water of condensation is fed as soon as the hydrostatic pressure in drop-leg in connection with the steam-pressure in the pipes is sufficient to overcome the boiler-pressure. The action of the device depends on the following principles: Difference of pressure may be balanced by a water-column; vapors or liquids tend to flow to the point of lowest pressure; rate of flow depends on difference of pressure and mass; decrease of static pressure in a steam-pipe or chamber is proportional to rate of condensation; in a steam-current water will be carried or swept along rapidly by friction. (Illustrated in *Modern Mechanism*, p. 807.)

**Loss from an Uncovered Steam-pipe.** (Bjorling on Pumping-engines.)—The amount of loss by condensation in a steam-pipe carried down a deep mine-shaft has been ascertained by actual practice at the Clay Cross Colliery, near Chesterfield, where there is a pipe  $7\frac{1}{2}$  in. internal diam., 1100 ft. long. The loss of steam by condensation was ascertained by direct measurement of the water deposited in a receiver, and was found to be equivalent to about 1 lb. of coal per I.H.P. per hour for every 100 ft. of steam-pipe; but there is no doubt that if the pipes had been in the upcast shaft, and well covered with a good non-conducting material, the loss would have been less. (For Steam-pipe Coverings, see p. 469, *ante*.)

## THE STEAM-BOILER.

**The Horse-power of a Steam-boiler.**—The term horse power has two meanings in engineering: *First, an absolute unit or measure of the rate of work*, that is, of the work done in a certain definite period of time, by a source of energy, as a steam-boiler, a waterfall, a current of air or water, or by a prime mover, as a steam-engine, a water-wheel, or a wind-mill. The value of this unit, whenever it can be expressed in foot-pounds of energy, as in the case of steam-engines, water-wheels, and waterfalls, is 33,000 foot-pounds per minute. In the case of boilers, where the work done, the conversion of water into steam, cannot be expressed in foot-pounds of available energy, the usual value given to the term horse-power is the evaporation of 30 lbs. of water of a temperature of 100° F. into steam at 70 lbs. pressure above the atmosphere. Both of these units are arbitrary; the first, 33,000 foot-pounds per minute, first adopted by James Watt, being considered equivalent to the power exerted by a good London draught-horse, and the 30 lbs. of water evaporated per hour being considered to be the steam requirement per indicated horse-power of an average engine.

The second definition of the term horse-power is *an approximate measure of the size, capacity, value, or "rating" of a boiler, engine, water-wheel, or other source or conveyer of energy*, by which measure it may be described, bought and sold, advertised, etc. No definite value can be given to this measure, which varies largely with local custom or individual opinion of makers and users of machinery. The nearest approach to uniformity which can be arrived at in the term "horse-power," used in this sense, is to say that a boiler, engine, water-wheel, or other machine, "rated" at a certain horse-power, should be capable of steadily developing that horse-power for a long period of time under ordinary conditions of use and practice, leaving to local custom, to the judgment of the buyer and seller, to written contracts of purchase and sale, or to legal decisions upon such contracts, the interpretation of what is meant by the term "ordinary conditions of use and practice." (Trans. A. S. M. E., vol. vii. p. 226.)

The committee of the A. S. M. E. on Trials of Steam-boilers in 1884 (Trans., vol. vi. p. 265) discussed the question of the horse-power of boilers as follows:

The Committee of Judges of the Centennial Exhibition, to whom the trials of competing boilers at that exhibition were intrusted, met with this same problem, and finally agreed to solve it, at least so far as the work of that committee was concerned, by the adoption of the unit, 30 lbs. of water evaporated into dry steam per hour from feed-water at 100° F., and under a pressure of 70 lbs. per square inch above the atmosphere, these conditions being considered by them to represent fairly average practice. The quantity of heat demanded to evaporate a pound of water under these conditions is 1110.2 British thermal units, or 1.1496 units of evaporation. The unit of power proposed is thus equivalent to the development of 33,305 heat-units per hour, or 34,488 units of evaporation. . . .

Your committee, after due consideration, has determined to accept the Centennial Standard, the first above mentioned, and to recommend that in all standard trials the commercial horse-power be taken as an evaporation of 30 lbs. of water per hour from a feed-water temperature of 100° F. into steam at 70 lbs. gauge pressure, which shall be considered to be equal to 34½ units of evaporation, that is, to 34½ lbs. of water evaporated from a feed-water temperature of 212° F. into steam at the same temperature. This standard is equal to 33,305 thermal units per hour.

It is the opinion of this committee that a boiler rated at any stated number of horse-powers should be capable of developing that power with easy firing, moderate draught, and ordinary fuel, while exhibiting good economy; and further, that the boiler should be capable of developing at least one third more than its rated power to meet emergencies at times when maximum economy is not the most important object to be attained.

**Unit of Evaporation.**—It is the custom to reduce results of boiler-tests to the common standard of weight of water evaporated by the unit weight of the combustible portion of the fuel, the evaporation being considered to have taken place at mean atmospheric pressure, and at the temperature due that pressure, the feed-water being also assumed to have been supplied at that temperature. This is, in technical language, said to be the equivalent evaporation from and at the boiling point at atmospheric pressure, or "from and at 212° F." This unit of evaporation, or one pound of

water evaporated from and at 212°, is equivalent to 965.7 British thermal units.

**Measures for Comparing the Duty of Boilers.**—The measure of the efficiency of a boiler is the number of pounds of water evaporated per pound of combustible, the evaporation being reduced to the standard of “from and at 212°;” that is, the equivalent evaporation from feed-water at a temperature of 212° F. into steam at the same temperature.

The measure of the capacity of a boiler is the amount of “boiler horse-power” developed, a horse-power being defined as the evaporation of 30 lbs. of water per hour from 100° F. into steam at 70 lbs. pressure, or 34½ lbs. per hour from and at 212°.

The measure of relative rapidity of steaming of boilers is the number of pounds of water evaporated per hour per square foot of water-heating surface.

The measure of relative rapidity of combustion of fuel in boiler-furnaces is the number of pounds of coal burned per hour per square foot of grate-surface.

### STEAM-BOILER PROPORTIONS.

**Proportions of Grate and Heating Surface required for a given Horse-power.**—The term horse-power here means capacity to evaporate 30 lbs. of water from 100° F., temperature of feed-water, to steam of 70 lbs., gauge-pressure = 34.5 lbs. from and at 212° F.

Average proportions for maximum economy for land boilers fired with good anthracite coal:

Heating surface per horse-power.....	11.5 sq. ft.
Grate “ “ “ “ .....	1/3 “
Ratio of heating to grate surface.....	34.5 “
Water evap'd from and at 212° per sq. ft. H.S. per hour	3 lbs.
Combustible burned per H.P. per hour.....	3 “
Coal with 1/6 refuse, lbs. per H.P. per hour.....	3.6 “
Combustible burned per sq. ft. grate per hour.....	9 “
Coal with 1/6 refuse, lbs. per sq. ft. grate per hour....	10.8 “
Water evap'd from and at 212° per lb. combustible... “ “ “ “ “ “ “ “ coal (1/6 refuse)	11.5 “ 9.6 “

The rate of evaporation is most conveniently expressed in pounds evaporated from and at 212° per sq. ft. of water-heating surface per hour, and the rate of combustion in pounds of coal per sq. ft. of grate-surface per hour.

**Heating-surface.**—For maximum economy with any kind of fuel a boiler should be proportioned so that at least one square foot of heating-surface should be given for every 3 lbs. of water to be evaporated from and at 212° F. per hour. Still more liberal proportions are required if a portion of the heating-surface has its efficiency reduced by: 1. Tendency of the heated gases to short-circuit, that is, to select passages of least resistance and flow through them with high velocity, to the neglect of other passages. 2. Deposition of soot from smoky fuel. 3. Incrustation. If the heating-surfaces are clean, and the heated gases pass over it uniformly, little if any increase in economy can be obtained by increasing the heating-surface beyond the proportion of 1 sq. ft. to every 3 lbs. of water to be evaporated, and with all conditions favorable but little decrease of economy will take place if the proportion is 1 sq. ft. to every 4 lbs. evaporated; but in order to provide for driving of the boiler beyond its rated capacity, and for possible decrease of efficiency due to the causes above named, it is better to adopt 1 sq. ft. to 3 lbs. evaporation per hour as the minimum standard proportion.

Where economy may be sacrificed to capacity, as where fuel is very cheap, it is customary to proportion the heating-surface much less liberally. The following table shows approximately the relative results that may be expected with different rates of evaporation, with anthracite coal.

Lbs. water evapor'd from and at 212° per sq. ft. heating-surface per hour:										
2	2.5	3	3.5	4	5	6	7	8	9	10
Sq. ft. heating-surface required per horse-power:										
17.3	13.8	11.5	9.8	8.6	6.8	5.8	4.9	4.3	3.8	3.5
Ratio of heating to grate surface if 1/3 sq. ft. of G. S. is required per H.P.:										
52	41.4	34.5	29.4	25.8	20.4	17.4	13.7	12.9	11.4	10.5
Probable relative economy:										
100	100	100	95	90	85	80	75	70	65	60
Probable temperature of chimney gases, degrees F.:										
450	450	450	518	585	652	720	787	855	922	990

The relative economy will vary not only with the amount of heating-surface per horse-power, but with the efficiency of that heating-surface as regards its capacity for transfer of heat from the heated gases to the water, which will depend on its freedom from soot and incrustation, and upon the circulation of the water and the heated gases.

With bituminous coal the efficiency will largely depend upon the thoroughness with which the combustion is effected in the furnace.

The efficiency with any kind of fuel will greatly depend upon the amount of air supplied to the furnace in excess of that required to support combustion. With strong draught and thin fires this excess may be very great, causing a serious loss of economy.

**Measurement of Heating-surface.**—Authorities are not agreed as to the methods of measuring the heating-surface of steam-boilers. The usual rule is to consider as heating-surface all the surfaces that are surrounded by water on one side and by flame or heated gases on the other, but there is a difference of opinion as to whether tubular heating-surface should be figured from the inside or from the outside diameter. Some writers say, measure the heating-surface always on the smaller side—the fire side of the tube in a horizontal return tubular boiler and the water side in a water-tube boiler. Others would deduct from the heating-surface thus measured an allowance for portions supposed to be ineffective on account of being covered by dust, or being out of the direct current of the gases.

It has hitherto been the common practice of boiler-makers to consider all surfaces as heating-surfaces which transmit heat from the flame or gases to the water, making no allowance for different degrees of effectiveness; also, to use the external instead of the internal diameter of tubes, for greater convenience in calculation, the external diameter of boiler-tubes usually being made in even inches or half inches. This method, however, is inaccurate, for the true heating-surface of a tube is the side exposed to the hot gases, the inner surface in a fire-tube boiler and the outer surface in a water-tube boiler. The resistance to the passage of heat from the hot gases on one side of a tube or plate to the water on the other consists almost entirely of the resistance to the passage of the heat from the gases into the metal, the resistance of the metal itself and that of the wetted surface being practically nothing. See paper by C. W. Baker, Trans. A. S. M. E., vol. xix.

**RULE for finding the heating-surface of vertical tubular boilers:** Multiply the circumference of the fire-box (in inches) by its height above the grate; multiply the combined circumference of all the tubes by their length, and to these two products add the area of the lower tube-sheet; from this sum subtract the area of all the tubes, and divide by 144: the quotient is the number of square feet of heating-surface.

**RULE for finding the heating-surface of horizontal tubular boilers:** Take the dimensions in inches. Multiply two thirds of the circumference of the shell by its length; multiply the sum of the circumferences of all the tubes by their common length; to the sum of these products add two thirds of the area of both tube-sheets; from this sum subtract twice the combined area of all the tubes; divide the remainder by 144 to obtain the result in square feet.

**RULE for finding the square feet of heating-surface in tubes:** Multiply the number of tubes by the diameter of a tube in inches, by its length in feet, and by .2618.

**Horse-power, Builder's Rating. Heating-surface per Horse-power.**—It is a general practice among builders to furnish about 12 square feet of heating-surface per horse-power, but as the practice is not uniform, bids and contracts should always specify the amount of heating-surface to be furnished. Not less than one third square foot of grate-surface should be furnished per horse-power.

*Engineering News*, July 5, 1894, gives the following rough-and-ready rule for finding approximately the commercial horse-power of tubular or water-tube boilers: Number of tubes  $\times$  their length in feet  $\times$  their nominal diameter in inches  $\div 50 = nLd \div 50$ . The number of square feet of surface

in the tubes is  $\frac{n\pi dL}{12} = \frac{nLd}{3.82}$ , and the horse-power at 12 square feet of surface

of tubes per horse-power, not counting the shell,  $= nLd \div 45.8$ . If 15 square feet of surface of tubes be taken, it is  $nLd \div 57.3$ . Making allowance for the heating-surface in the shell will reduce the divisor to about 50.

**Horse-power of Marine and Locomotive Boilers.**—The term horse-power is not generally used in connection with boilers in marine practice, or with locomotives. The boilers are designed to suit the engines, and are rated by extent of grate and heating-surface only.

**Grate-surface.**—The amount of grate-surface required per horse power, and the proper ratio of heating-surface to grate-surface are extremely variable, depending chiefly upon the character of the coal and upon the rate of draught. With good coal, low in ash, approximately equal results may be obtained with large grate-surface and light draught and with small grate-surface and strong draught, the total amount of coal burned per hour being the same in both cases. With good bituminous coal, like Pittsburgh, low in ash, the best results apparently are obtained with strong draught and high rates of combustion, provided the grate-surfaces are cut down so that the total coal burned per hour is not too great for the capacity of the heating-surface to absorb the heat produced.

With coals high in ash, especially if the ash is easily fusible, tending to choke the grates, large grate-surface and a slow rate of combustion are required, unless means, such as shaking grates, are provided to get rid of the ash as fast as it is made.

The amount of grate-surface required per horse-power under various conditions may be estimated from the following table :

	Lbs. Water from and at 212° per lb. Coal.	Lbs. Coal per H.P. per hour.	Pounds of Coal burned per square foot of Grate per hour.								
			8	10	12	15	20	25	30	35	40
			Sq. Ft. Grate per H. P.								
Good coal and boiler,	10	3.45	.43	.35	.28	.23	.17	.14	.11	.10	.09
	9	3.83	.48	.38	.32	.25	.19	.15	.13	.11	.10
Fair coal or boiler,	8.61	4.	.50	.40	.33	.26	.20	.16	.13	.12	.10
	8	4.31	.54	.43	.36	.29	.22	.17	.14	.13	.11
	7	4.93	.62	.49	.41	.33	.24	.20	.17	.14	.12
Poor coal or boiler,	6.9	5.	.63	.50	.42	.34	.25	.20	.17	.15	.13
	6	5.75	.72	.58	.48	.38	.29	.23	.19	.17	.14
	5	6.9	.86	.69	.58	.46	.35	.28	.23	.22	.17
Lignite and poor boiler,	3.45	10.	1.25	1.00	.83	.67	.50	.40	.33	.29	.25

In designing a boiler for a given set of conditions, the grate-surface should be made as liberal as possible, say sufficient for a rate of combustion of 10 lbs. per square foot of grate for anthracite, and 15 lbs. per square foot for bituminous coal, and in practice a portion of the grate-surface may be bricked over if it is found that the draught, fuel, or other conditions render it advisable.

#### Proportions of Areas of Flues and other Gas-passages.

—Rules are usually given making the area of gas-passages bear a certain ratio to the area of the grate-surface; thus a common rule for horizontal tubular boilers is to make the area over the bridge wall  $1/7$  of the grate-surface, the flue area  $1/8$ , and the chimney area  $1/9$ .

For average conditions with anthracite coal and moderate draught, say a rate of combustion of 12 lbs. coal per square foot of grate per hour, and a ratio of heating to grate surface of 30 to 1, this rule is as good as any, but it is evident that if the draught were increased so as to cause a rate of combustion of 24 lbs., requiring the grate-surface to be cut down to a ratio of 60 to 1, the areas of gas-passages should not be reduced in proportion. The amount of coal burned per hour being the same under the changed conditions, and there being no reason why the gases should travel at a higher velocity, the actual areas of the passages should remain as before, but the ratio of the area to the grate-surface would in that case be doubled.

Mr. Barrus states that the highest efficiency with anthracite coal is obtained when the tube area is  $1/9$  to  $1/10$  of the grate-surface, and with bituminous coal when it is  $1/6$  to  $1/7$ , for the conditions of medium rates of combustion, such as 10 to 12 lbs. per square foot of grate per hour, and 12 square feet of heating-surface allowed to the horse-power.

The tube area should be made large enough not to choke the draught, and so lessen the capacity of the boiler; if made too large the gases are apt to select the passages of least resistance and escape from them at a high velocity and high temperature.

This condition is very commonly found in horizontal tubular boilers where

the gases go chiefly through the upper rows of tubes; sometimes also in vertical tubular boilers, where the gases are apt to pass most rapidly through the tubes nearest to the centre.

**Air-passages through Grate-bars.**—The usual practice is, air-opening = 30% to 50% of area of the grate; the larger the better, to avoid stoppage of the air-supply by clinker; but with coal free from clinker much smaller air-space may be used without detriment. See paper by F. A. Scheffler, Trans. A. S. M. E., vol. xv. p. 503.

**PERFORMANCE OF BOILERS.**

The performance of a steam-boiler comprises both its capacity for generating steam and its economy of fuel. Capacity depends upon size, both of grate-surface and of heating-surface, upon the kind of coal burned, upon the draft, and also upon the economy. Economy of fuel depends upon the completeness with which the coal is burned in the furnace, on the proper regulation of the air-supply to the amount of coal burned, and upon the thoroughness with which the boiler absorbs the heat generated in the furnace. The absorption of heat depends on the extent of heating-surface in relation to the amount of coal burned or of water evaporated, upon the arrangement of the gas-passages, and upon the cleanness of the surfaces. The capacity of a boiler may increase with increase of economy when this is due to more thorough combustion of the coal or to better regulation of the air-supply, or it may increase at the expense of economy when the increased capacity is due to overdriving, causing an increased loss of heat in the chimney gases. The relation of capacity to economy is therefore a complex one, depending on many variable conditions.

Many attempts have been made to construct a formula expressing the relation between capacity, rate of driving, or evaporation per square foot of heating-surface, to the economy, or evaporation per pound of combustible, but none of them can be considered satisfactory, since they make the economy depend only on the rate of driving (a few so-called "constants," however, being introduced in some of them for different classes of boilers, kinds of fuel, or kind of draft), and fail to take into consideration the numerous other conditions upon which economy depends. Such formulæ are Rankine's, Clark's, Emery's, Isherwood's, Carpenter's, and Hale's. A discussion of them all may be found in Mr. R. S. Hale's paper on "Efficiency of Boiler Heating Surface," in Trans. A. S. M. E., vol. xviii. p. 328. Mr. Hale's formula takes into account the effect of radiation, which reduces the economy considerably when the rate of driving is less than 3 lbs. per square foot of heating-surface per hour.

Selecting the highest results obtained at different rates of driving obtained with anthracite coal in the Centennial tests (see p. 685), and the highest results with anthracite reported by Mr. Barrus in his book on Boiler Tests, the author has plotted two curves showing the maximum results which may be expected with anthracite coal, the first under exceptional conditions such as obtained in the Centennial tests, and the second under the best conditions of ordinary practice. (Trans. A. S. M. E., xviii. 354). From these curves the following figures are obtained.

Lbs. water evaporated from and at 212° per sq. ft. heating-surface per hour:

1.6	1.7	2	2.6	3	3.5	4	4.5	5	6	7	8
-----	-----	---	-----	---	-----	---	-----	---	---	---	---

Lbs. water evaporated from and at 212° per lb. combustible:

Centennial.	11.8	11.9	12.0	12.1	12.05	12	11.85	11.7	11.5	10.85	9.8	8.5
Barrus.....	11.4	11.5	11.55	11.6	11.6	11.5	11.2	10.9	10.6	9.9	9.2	8.5
Avg. Cent'l ....	.....	.....	12.0	11.6	11.2	10.8	10.4	10.0	9.6	8.8	8.0	7.2

The figures in the last line are taken from a straight line drawn as nearly as possible through the average of the plotting of all the Centennial tests. The poorest results are far below these figures. It is evident that no formula can be constructed that will express the relation of economy to rate of driving as well as do the three lines of figures given above.

For semi-bituminous and bituminous coals the relation of economy to the rate of driving no doubt follows the same general law that it does with anthracite, i.e., that beyond a rate of evaporation of 3 or 4 lbs. per sq. ft. of heating-surface per hour there is a decrease of economy, but the figures obtained in different tests will show a wider range between maximum and average results on account of the fact that it is more difficult with bituminous than with anthracite coal to secure complete combustion in the furnace.

The amount of the decrease in economy due to driving at rates exceeding 4 lbs. of water evaporated per square foot of heating-surface per hour differs greatly with different boilers, and with the same boiler it may differ with different settings and with different coal. The arrangement and size of the gas-passages seem to have an important effect upon the relation of economy to rate of driving. There is a large field for future research to determine the causes which influence this relation.

**General Conditions which secure Economy of Steam-boilers.**—In general, the highest results are produced where the temperature of the escaping gases is the least. An examination of this question is made by Mr. G. H. Barrus in his book on "Boiler Tests," by selecting those tests made by him, six in number, in which the temperature exceeds the average, that is, 375° F., and comparing with five tests in which the temperature is less than 375°. The boilers are all of the common horizontal type, and all use anthracite coal of either egg or broken size. The average flue temperatures in the two series was 444° and 343° respectively, and the difference was 101°. The average evaporations are 10.40 lbs. and 11.02 lbs. respectively, and the lowest result corresponds to the case of the highest flue temperature. In these tests it appears, therefore, that a reduction of 101° in the temperature of the waste gases secured an increase in the evaporation of 6%. This result corresponds quite closely to the effect of lowering the temperature of the gases by means of a flue-heater where a reduction of 107° was attended by an increase of 7% in the evaporation per pound of coal.

A similar comparison was made on horizontal tubular boilers using Cumberland coal. The average flue temperature in four tests is 450° and the average evaporation is 11.34 lbs. Six boilers have temperatures below 415°, the average of which is 383°, and these give an average evaporation of 11.75 lbs. With 67° less temperature of the escaping gases the evaporation is higher by about 4%.

The wasteful effect of a high flue temperature is exhibited by other boilers than those of the horizontal tubular class. This source of waste was shown to be the main cause of the low economy produced in those vertical boilers which are deficient in heating-surface.

*Relation between the Heating-surface and Grate-surface to obtain the Highest Efficiency.*—A comparison of three tests of horizontal tubular boilers with anthracite coal, the ratio of heating-surface to grate-surface being 36.4 to 1, with three other tests of similar boilers, in which the ratio was 48 to 1, showed practically no difference in the results. The evidence shows that a ratio of 36 to 1 provides a sufficient quantity of heating-surface to secure the full efficiency of anthracite coal where the rate of combustion is not more than 12 lbs. per sq. ft. of grate per hour.

In tests with bituminous coal an increase in the ratio from 36.8 to 42.8 secured a small improvement in the evaporation per pound of coal, and a high temperature of the escaping gases indicated that a still further increase would be beneficial. Among the high results produced on common horizontal tubular boilers using bituminous coal, the highest occurs where the ratio is 53.1 to 1. This boiler gave an evaporation of 12.47 lbs. A double-deck boiler furnishes another example of high performance, an evaporation of 12.42 lbs. having been obtained with bituminous coal, and in this case the ratio is 65 to 1. These examples indicate that a much larger amount of heating-surface is required for obtaining the full efficiency of bituminous coal than for boilers using anthracite coal. The temperature of the escaping gases in the same boiler is invariably higher when bituminous coal is used than when anthracite coal is used. The deposit of soot on the surfaces when bituminous coal is used interferes with the full efficiency of the surface, and an increased area is demanded as an offset to the loss which this deposit occasions. It would seem, then, that if a ratio of 36 to 1 is sufficient for anthracite coal, from 45 to 50 should be provided when bituminous coal is burned, especially in cases where the rate of combustion is above 10 or 12 lbs. per sq. ft. of grate per hour.

The number of tubes controls the ratio between the area of grate-surface and area of tube-opening. A certain minimum amount of tube-opening is required for efficient work.

The best results obtained with anthracite coal in the common horizontal boiler are in cases where the ratio of area of grate-surface to area of tube-opening is larger than 9 to 1. The conclusion is drawn that the highest efficiency with anthracite coal is obtained when the tube-opening is from 1/9 to 1/10 of the grate-surface.

When bituminous coal is burned the requirements appear to be different. The effect of a large tube-opening does not seem to make the extra tubes inefficient when bituminous coal is used. The highest result on any boiler of the horizontal tubular class, fired with bituminous coal, was obtained where the tube-opening was the largest. This gave an evaporation of 12.47 lbs., the ratio of grate-surface to tube-opening being 5.4 to 1. The next highest result was 12.42 lbs., the ratio being 5.2 to 1. Three high results, averaging 12.01 lbs., were obtained when the average ratio was 7.1 to 1. Without going to extremes, the ratio to be desired when bituminous coal is used is that which gives a tube-opening having an area of from 1/6 to 1/7 of the grate-surface. This applies to medium rates of combustion of, say, 10 to 12 lbs. per sq. ft. of grate per hour, 12 sq. ft. of water-heating surface being allowed per horse-power.

A comparison of results obtained from different types of boilers leads to the general conclusion that the economy with which different types of boilers operate depends much more upon their proportions and the conditions under which they work, than upon their type; and, moreover, that when these proportions are suitably carried out, and when the conditions are favorable, the various types of boilers give substantially the same economic result.

**Efficiency of a Steam-boiler.**—The efficiency of a boiler is the percentage of the total heat generated by the combustion of the fuel which is utilized in heating the water and in raising steam. With anthracite coal the heating-value of the combustible portion is very nearly 14,500 B. T. U. per lb., equal to an evaporation from and at 212° of  $14,500 \div 966 = 15$  lbs. of water. A boiler which when tested with anthracite coal shows an evaporation of 12 lbs. of water per lb. of combustible, has an efficiency of  $12 \div 15 = 80\%$ , a figure which is approximated, but scarcely ever quite reached, in the best practice. With bituminous coal it is necessary to have a determination of its heating-power made by a coal calorimeter before the efficiency of the boiler using it can be determined, but a close estimate may be made from the chemical analysis of the coal. (See Coal.)

The difference between the efficiency obtained by test and 100% is the sum of the numerous wastes of heat, the chief of which is the necessary loss due to the temperature of the chimney-gases. If we have an analysis and a calorimetric determination of the heating-power of the coal (properly sampled), and an average analysis of the chimney-gases, the amounts of the several losses may be determined with approximate accuracy by the method described below.

Data given :

1. ANALYSIS OF THE COAL.		2. ANALYSIS OF THE DRY CHIMNEY-GASES, BY WEIGHT.				
Cumberland Semi-bituminous.						
Carbon.....	80.55		C.	O.	N.	
Hydrogen.....	4.50	CO <sub>2</sub> = 13.6 =	3.71	9.89	.....	
Oxygen.....	2.70	CO = .2 =	.09	.11	.....	
Nitrogen.....	1.08	O = 11.2 =	....	11.20	.....	
Moisture.....	2.92	N = 75.0 =	....	....	75.00	
Ash.....	8.25					
	100.00		100.0	3.80	21.20	75.00

Heating-value of the coal by Dulong's formula, 14,243 heat-units.

The gases being collected over water, the moisture in them is not determined.

3. Ash and refuse as determined by boiler-test, 10.25, or 2% more than that found by analysis, the difference representing carbon in the ashes obtained in the boiler-test.

4. Temperature of external atmosphere, 60° F.

5. Relative humidity of air, 60%, corresponding (see air tables) to .007 lb. of vapor in each lb. of air.

6. Temperature of chimney-gases, 560° F.

Calculated results :

The carbon in the chimney-gases being 3.8% of their weight, the total weight of dry gases per lb. of carbon burned is  $100 \div 3.8 = 26.32$  lbs. Since the carbon burned is  $80.55 - 2 = 78.55\%$  of the weight of the coal, the weight of the dry gases per lb. of coal is  $26.32 \times 78.55 \div 100 = 20.67$  lbs.

Each pound of coal furnishes to the dry chimney-gases .7855 lb. C, .0108N, and  $(2.70 - \frac{4.50}{8}) \div 100 = .0214$  lb. O; a total of .8177, say .82 lb. This sub-

tracted from 20.67 lbs. leaves 19.85 lbs. as the quantity of dry air (not including moisture) which enters the furnace per pound of coal, not counting the air required to burn the available hydrogen, that is, the hydrogen minus one eighth of the oxygen chemically combined in the coal. Each lb. of coal burned contained .045 lb. H, which requires  $.045 \times 8 = .36$  lb. O for its combustion. Of this, .027 lb. is furnished by the coal itself, leaving .333 lb. to come from the air. The quantity of air needed to supply this oxygen (air containing 23% by weight of oxygen) is  $.333 \div .23 = 1.45$  lb., which added to the 19.85 lbs. already found gives 21.30 lbs. as the quantity of dry air supplied to the furnace per lb. of coal burned.

The air carried in as vapor is .0071 lb. for each lb. of dry air, or  $21.3 \times .0071 = 0.15$  lb. for each lb. of coal. Each lb. of coal contained .029 lb. of moisture, which was evaporated and carried into the chimney-gases. The .045 lb. of H per lb. of coal when burned formed  $.045 \times 9 = .405$  lb. of  $H_2O$ .

From the analysis of the chimney-gas it appears that  $.09 \div 3.80 = 2.37\%$  of the carbon in the coal was burned to CO instead of to  $CO_2$ .

We now have the data for calculating the various losses of heat, as follows, for each pound of coal burned:

	Heat- units.	Per cent of Heat-value of the Coal.
20.67 lbs. dry gas $\times (560^\circ - 60^\circ) \times$ sp. heat 0.24	= 2480.4	17.41
.15 lb. vapor in air $\times (560^\circ - 60^\circ) \times$ sp. heat .48	= 36.0	0.25
.029 lb. moisture in coal heated from $60^\circ$ to $212^\circ$	= 4.4	0.03
“ evaporated from and at $212^\circ$ ; $.029 \times 966$	= 28.0	0.20
“ steam (heated from $212^\circ$ to $560^\circ$ ) $\times 348 \times .48$	= 4.8	0.03
.405 lb. $H_2O$ from H in coal $\times (152 + 966 + 348 \times .48)$	= 520.4	3.65
.0237 lb. C burned to CO; loss by incomplete combustion, $.0237 \times (14544 - 4451)$	= 239.2	1.68
.02 lb. coal lost in ashes; $.02 \times 14544$	= 290.9	2.04
Radiation and unaccounted for, by difference	= 624.0	4.31
	<hr/> 4228.1	<hr/> 29.68
Utilized in making steam, equivalent evaporation		
10.37 lbs. from and at $212^\circ$ per lb. of coal	= 10,014.9	70.32
	<hr/> 14,243.0	<hr/> 100.00

The heat lost by radiation from the boiler and furnace is not easily determined directly, especially if the boiler is enclosed in brickwork, or is protected by non-conducting covering. It is customary to estimate the heat lost by radiation by difference, that is, to charge radiation with all the heat lost which is not otherwise accounted for.

One method of determining the loss by radiation is to block off a portion of the grate-surface and build a small fire on the remainder, and drive this fire with just enough draught to keep up the steam-pressure and supply the heat lost by radiation without allowing any steam to be discharged, weighing the coal consumed for this purpose during a test of several hours' duration.

Estimates of radiation by difference are apt to be greatly in error, as in this difference are accumulated all the errors of the analyses of the coal and of the gases. An average value of the heat lost by radiation from a boiler set in brickwork is about 4 per cent. When several boilers are in a battery and enclosed in a boiler-house the loss by radiation may be very much less, since much of the heat radiated from the boiler is returned to it in the air supplied to the furnace, which is taken from the boiler-room.

An important source of error in making a "heat balance" such as the one above given, especially when highly bituminous coal is used, may be due to the non-combustion of part of the hydrocarbon gases distilled from the coal immediately after firing, when the temperature of the furnace may be reduced below the point of ignition of the gases. Each pound of hydrogen which escapes burning is equivalent to a loss of heat in the furnace of 62,500 heat-units.

In analyzing the chimney gases by the usual method the percentages of the constituent gases are obtained by volume instead of by weight. To reduce percentages by volume to percentages by weight, multiply the percentage by volume of each gas by its specific gravity as compared with air, and divide each product by the sum of the products.

If O, CO, CO<sub>2</sub>, and N represent the per cents by volume of oxygen, carbonic oxide, carbonic acid, and nitrogen, respectively, in the gases of combustion:

$$\left. \begin{array}{l} \text{Lbs. of air required to burn} \\ \text{one pound of carbon} \end{array} \right\} = \frac{3.032 N}{\text{CO}_2 + \text{CO}}$$

$$\text{Ratio of total air to the theoretical requirement} = \frac{N}{N - 3.782 O}$$

$$\left. \begin{array}{l} \text{Lbs. of air per pound} \\ \text{of coal} \end{array} \right\} = \left\{ \begin{array}{l} \text{Lbs. of air per pound} \\ \text{of carbon} \end{array} \right\} \times \left\{ \begin{array}{l} \text{Per cent of carbon} \\ \text{in coal.} \end{array} \right.$$

$$\text{Lbs. dry gas produced per pound of carbon} = \frac{11\text{CO}_2 + 8\text{O} + 7(\text{CO} + \text{N})}{3(\text{CO}_2 + \text{CO})}$$

**TESTS OF STEAM-BOILERS.**

**Boiler-tests at the Centennial Exhibition, Philadelphia, 1876.**—(See Reports and Awards Group XX, International Exhibition, Phila., 1876; also, Clark on the Steam-engine, vol. i, page 253.)

Competitive tests were made of fourteen boilers, using good anthracite coal, one boiler, the Galloway, being tested with both anthracite and semi-bituminous coal. Two tests were made with each boiler: one called the capacity trial, to determine the economy and capacity at a rapid rate of driving; and the other called the economy trial, to determine the economy when driven at a rate supposed to be near that of maximum economy and rated capacity. The following table gives the principal results obtained in the economy trial, together with the capacity and economy figures of the capacity trial for comparison.

Name of Boiler.	Economy Tests.								Capacity Tests.		
	Ratio Water-heating Surface to Grate-surface.	Coal burned per sq. ft. Grate per hour.	Per cent Ash and Refuse.	Water evap. from 100° to 70 lbs. p. s.ft. H.S. per hr. The comparison of the economy and capacity trials shows that an average increase in capacity of 30 per cent was attended by a decrease in economy of 8 per cent, but the relation of economy to rate of driving varied greatly in the different boilers. In the Kelly boiler an increase in capacity of 22 per cent was attended by a decrease in economy of over 18 per cent, while the Smith boiler with an increase of 25 per cent in capacity showed a slight increase in economy.

One of the most important lessons gained from the above tests is that there is no necessary relation between the type of a boiler and economy. Of the five boilers that gave the best results, the total range of variation between the highest and lowest of the five being only 2.3%, three were water-tube boilers, one was a horizontal tubular boiler, and the fifth was a combination of the two types. The next boiler on the list, the Galloway, was an internally fired boiler, all of the others being externally fired. The following is a brief description of the principal constructive features of the fourteen boilers:

Root.....	}	4-in. water-tubes, inclined 20° to horizontal; reversed draught.
Firmenich.....		3-in. water-tubes, nearly vertical; reversed draught.
Lowe.....	}	Cylindrical shell, multitubular flue.
Smith.....		Cylindrical shell, multitubular flue--water-tubes in side flues.
Babcock & Wilcox....	}	3½-in. water-tubes, inclined 15° to horizontal; reversed draught.
Galloway.....		Cylindrical shell, furnace-tubes and water-tubes.
Andrews.....	}	Square fire-box and double return multitubular flues.
Harrison.....		8 slabs of cast-iron spheres, 8 in. in diameter; reversed draught.
Wiegand.....	}	4-in. water-tubes, vertical, with internal circulating tubes.
Anderson.....		3-in. flue-tubes, nearly horizontal; return circulation.
Kelly.....	}	3-in. water-tubes, slightly inclined; each divided by internal diaphragm to promote circulation.
Exeter.....		27 hollow rectangular cast-iron slabs.
Pierce.....	}	Rotating horizontal cylinder, with flue-tubes.
Rogers & Black.....		Vertical cylindrical boiler, with external water-tubes.

**Tests of Tubulous Boilers.**—The following tables are given by S. H. Leonard, Asst. Engr. U. S. N., in *Jour. Am. Soc. Naval Engrs.* 1890. The tests were made at different times by boards of U. S. Naval Engineers, except the test of the locomotive-torpedo boiler, which was made in England.

\* Diameter. † Diam. of drum. ‡ Approximate.

The weight per I.H.P. is estimated on a basis of 20 lbs. of water per hour for all cases excepting the Scotch boiler, where 25 lbs. have been used, as this boiler was limited to 80 lbs. pressure of steam.

The following approximation is made from the large table, on the assumption that the evaporation varies directly as the combustion, and 25 lbs. of coal per square foot of grate per hour used as the unit.

Type of Boiler.	Com bustion.	Evapora- tion per cu. ft. of Space.	Weight per I.H.P.	Weight per sq. ft. Heating- surface.	Weight per lb. Water Evapora- ted.
Belleville .....	0.50	0.50	2.02	2.10	2.50
Herreshoff.....	1.00	0.95	0.72	0.60	0.90
Towne.....	1.00	1.20	1.12	0.87	1.30
Scotch.....	1.00	0.44	2.40	1.64	2.30
Locomotive .....	3.90	0.31	3.70	1.25	3.50
Ward .....	2.20	0.58	1.27	0.50	1.53

The Belleville boiler has no practical advantage over the Scotch either in space occupied or weight. All the other tubulous boilers given greatly exceed the Scotch in these advantages of weight and space.

**Some High Rates of Evaporation.**—*Eng'g*, May 9, 1884, p. 415.

	Locomotive.	Torpedo-boat.
Water evap. per sq. ft. H.S. per hour....	12.57	13.73
" " " lb. fuel from and at 212°.	8.22	8.94
Thermal units transf'd per sq. ft. of H.S.	12,142	13,263
Efficiency .....	.586	.637

It is doubtful if these figures were corrected for priming.

**Economy Effected by Heating the Air Supplied to Boiler-furnaces.** (Clark, S. E.)—Meunier and Scheurer-Kestner obtained about 7% greater evaporative efficiency in summer than in winter, from the same boilers under like conditions,—an excess which had been explained by the difference of loss by radiation and conduction. But Mr. Poupardin, surmising that the gain might be due in some degree also to the greater temperature of the air in summer, made comparative trials with two groups of three boilers, each working one week with the heated air, and the next week with cold air. The following were the several efficiencies:

**FIRST TRIALS: THREE BOILERS; RONCHAMP COAL.**

	Water per lb. of Coal.	Water per lb. of Combustible.
With heated air (128° F.) .....	7.77 lbs.	8.95 lbs.
With cold air (69° 8).....	7.33 "	8.63 "
Difference in favor of heated air ....	0.44 "	0.32 "

**SECOND TRIALS: SAME COAL; THREE OTHER BOILERS.**

With heated air (120° 4 F.).....	8.70 lbs.	10.08 lbs.
With cold air (75° 2).....	8.09 "	9.34 "
Difference in favor of heated air.....	0.61 "	0.74 "

These results show economies in favor of heating the air of 6% and 7½%.

Mr. Poupardin believes that the gain in efficiency is due chiefly to the better combustion of the gases with heated air. It was observed that with heated air the flames were much shorter and whiter, and that there was notably less smoke from the chimney.

An extensive series of experiments was made by J. C. Hoadley (Trans. A. S. M. E., vol. vi., 676) on a "Warm-blast Apparatus," for utilizing the heat of the waste gases in heating the air supplied to the furnace. The apparatus, as applied to an ordinary horizontal tubular boiler 60 in. diameter, 21 feet long, with 65 ¾-inch tubes, consisted of 240 2-inch tubes, 18 feet long, through which the hot gases passed while the air circulated around them. The net saving of fuel effected by the warm blast was from 10.7% to 15.5% of the fuel used with cold blast. The comparative temperatures averaged as follows, in degrees F.:

	Cold-blast Boiler.	Warm-blast Boiler.	Difference.
In heat of fire.....	2493	2793	300
At bridge wall.....	1340	1600	260
In smoke box.....	373	375	2
Air admitted to furnace.....	32	332	300
Steam and water in boiler.....	300	300	0
Gases escaping to chimney... ..	373	162	211
External air.....	32	32	0

With anthracite coal the evaporation from and at 212° per lb. combustible was, for the cold-blast boiler, days 10.85 lbs., days and nights 10.51; and for the warm-blast boiler, days 11.83, days and nights 11.03.

### Results of Tests of Heine Water-tube Boilers with Different Coals.

(Communicated by E. D. Meier, C.E., 1894.)

Efficiency of boiler per c.	77.0	74.3	78.5	67.2	62.5	69.3	73.0	72.6

Tests Nos. 7 and 8 were made with the Hawley Down-draught Furnace, the others with ordinary furnaces.

These tests confirm the statement already made as to the difficulty of obtaining, with ordinary grate-furnaces, as high a percentage of the calorific value of the fuel with the Western as with the Eastern coals.

Test No 3, 78.5% efficiency, is remarkably good for Pittsburgh (Youghiogh-eny) coal. If the Washington coal had given equal efficiency, the saving of fuel would be  $\frac{78.5 - 62.5}{78.5} = 20.2\%$ . The results of tests Nos. 7 and 8 indicate that the downward-draught furnace is well adapted for burning Illinois coals.

**Maximum Boiler Efficiency with Cumberland Coal.—**

About 12.5 lbs. of water per lb. combustible from and at 212° is about the highest evaporation that can be obtained from the best steam fuels in the United States, such as Cumberland, Pocalhontas, and Clearfield. In exceptional cases 13 lbs. has been reached, and one test is on record (F. W. Dean, *Eng'g News*, Feb. 1, 1894) giving 13.23 lbs. The boiler was internally fired, of the Belpaire type, 82 inches diameter, 31 feet long, with 160 3-inch tubes 12½ feet long. Heating-surface, 1998 square feet; grate-surface, 45 square feet, reduced during the test to 30½ square feet. Double furnace, with fire-brick arches and a long combustion-chamber. Feed-water heater in smoke-box. The following are the principal results :

	1st Test.	2d Test.
Dry coal burned per sq. ft. of grate per hour, lbs.....	8.85	16.06
Water evap. per sq. ft. of heating-surface per hour, lbs	1.63	3.00
Water evap. from and at 212° per lb. combustible, including feed-water heater.....	13.17	13.23
Water evaporated, excluding feed-water heater.....	12.88	12.90
Temperature of gases after leaving heater, F.....	360°	469°

**BOILERS USING WASTE GASES.**

**Proportioning Boilers for Blast-Furnaces.—**(F. W. Gordon, *Trans. A. I. M. E.*, vol. xii., 1883.)

Mr. Gordon's recommendation for proportioning boilers when properly set for burning blast-furnace gas is, for coke practice, 30 sq. ft. of heating-surface per ton of iron per 24 hours, which the furnace is expected to make, calculating the heating-surface thus : For double-flued boilers, all shell-surface exposed to the gases, and half the flue-surface; for the French type, all the exposed surface of the upper boiler and half the lower boiler-surface; for cylindrical boilers, not more than 60 ft. long, all the heating-surface.

To the above must be added a battery for relay in case of cleaning, repairs, etc., and more than one battery extra in large plants, when the water carries much lime.

For anthracite practice add 50% to above calculations. For charcoal practice deduct 20%.

In a letter to the author in May, 1894, Mr. Gordon says that the blast-furnace practice at the time when his article (from which the above extract is taken) was written was very different from that existing at the present time; besides, more economical engines are being introduced, so that less than 30 sq. ft. of boiler-surface per ton of iron made in 24 hours may now be adopted. He says further: Blast-furnace gases are seldom used for other than furnace requirements, which of course is throwing away good fuel. In this case a furnace in an ordinary good condition, and a condition where it can take its maximum of blast, which is in the neighborhood of 200 to 225 cubic ft., atmospheric measurement, per sq. ft. of sectional area of hearth, will generate the necessary H.P. with very small heating-surface, owing to the high heat of the escaping gases from the boilers, which frequently is 1000 degrees.

A furnace making 200 tons of iron a day will consume about 900 H.P. in blowing the engine. About a pound of fuel is required in the furnace per pound of pig metal.

In practice it requires 70 cu ft. of air-piston displacement per lb. of fuel consumed, or 22,400 cu. ft. per minute for 200 tons of metal in 1400 working minutes per day, at, say, 10 lbs. discharge-pressure. This is equal to 9¼ lbs. M.E.P. on the steam-piston of equal area to the blast-piston, or 900 I.H.P. To this add 20% for hoisting, pumping and other purposes for which steam is employed around blast-furnaces, and we have 1100 H.P., or say 5½ H.P. per ton of iron per day. Dividing this into 30 gives approximately 5½ sq. ft. of heating-surface of boiler per H.P.

**Water-tube Boilers using Blast-furnace Gases.—**D. S. Jacobus (*Trans. A. I. M. E.*, xvii. 50) reports a test of a water-tube boiler using blast-furnace gas as fuel. The heating-surface was 2535 sq. ft. It developed 328 H.P. (Centennial standard), or 5.01 lbs. of water from and at 212° per sq. ft. of heating-surface per hour. Some of the principal data obtained were as follows: Calorific value of 1 lb. of the gas, 1413 B T.U., including the effect of its initial temperature, which was 650° F. Amount of air used to burn 1 lb. of the gas = 0.9 lb. Chimney draught, 1½ in. of water. Area of gas inlet, 300 sq. in.; of air inlet, 100 sq. in. Temperature of the chimney

gases, 775° F. Efficiency of the boiler calculated from the temperatures and analyses of the gases at exit and entrance, 61%. The average analyses were as follows, hydrocarbons being included in the nitrogen :

	By Weight.		By Volume.	
	At Entrance.	At Exit.	At Entrance.	At Exit.

**Steam-boilers Fired with Waste Gases from Puddling and Heating Furnaces.**—The *Iron Age*, April 6, 1893, contains a report of a number of tests of steam-boilers utilizing the waste heat from puddling and heating furnaces in rolling-mills. The following principal data are selected: In Nos. 1, 2, and 4 the boiler is a Babcock & Wilcox water-tube boiler, and in No. 3 it is a plain cylinder boiler, 42 in. diam. and 26 ft. long. No. 4 boiler was connected with a heating-furnace, the others with puddling furnaces.

	No. 1.	No. 2.	No. 3.	No. 4.
Heating-surface, sq. ft.....	1026	1196	143	1380
Grate-surface, sq. ft.....	19.9	13 6	13.6	16.7
Ratio H.S. to G.S.....	52	87.2	10.5	82.8
Water evap. per hour, lbs.....	3358	2159	1812	3055
“ “ per sq. ft. H.S. per hr., lbs....	3.3	1.8	12.7	2.2
“ “ per lb. coal from and at 212°.	5.9	6.24	3.76	6.34
“ “ “ “ comb. “ “ “ “	....	7.20	4.31	8.34

In No. 2, 1.38 lbs. of iron were puddled per lb. of coal.

In No. 3, 1.14 lbs. of iron were puddled per lb. of coal.

No. 3 shows that an insufficient amount of heating-surface was provided for the amount of waste heat available.

## RULES FOR CONDUCTING BOILER-TESTS.

### Code of 1899.

(Reported by the Committee on Boiler Trials, Am. Soc. M. E.)\*

I. *Determine at the outset* the specific object of the proposed trial, whether it be to ascertain the capacity of the boiler, its efficiency as a steam-generator, its efficiency and its defects under usual working conditions, the economy of some particular kind of fuel, or the effect of changes of design, proportion, or operation; and prepare for the trial accordingly.

II. *Examine the boiler*, both outside and inside; ascertain the dimensions of grates, heating surfaces, and all important parts; and make a full record, describing the same, and illustrating special features by sketches.

III. *Notice the general condition* of the boiler and its equipment, and record such facts in relation thereto as bear upon the objects in view.

If the object of the trial is to ascertain the maximum economy or capacity of the boiler as a steam-generator, the boiler and all its appurtenances should be put in first-class condition. Clean the heating surface inside and outside, remove clinkers from the grates and from the sides of the furnace. Remove all dust, soot, and ashes from the chambers, smoke-connections, and flues. Close air-leaks in the masonry and poorly fitted cleaning-doors. See that the damper will open wide and close tight. Test for air-leaks by firing a few shovels of smoky fuel and immediately closing the damper, observing the escape of smoke through the crevices, or by passing the flame of a candle over cracks in the brickwork.

\* The code is here slightly abridged. The complete report of the Committee may be obtained in pamphlet form from the Secretary of the American Society of Mechanical Engineers, 12 West 31st St., New York.

Then

$$w + x = \text{weight of water leaving injector,}$$

$$x = w \frac{h_2 - h_1}{h_2 - h_3}.$$

See that the steam-main is so arranged that water of condensation cannot run back into the boiler.

VIII. *Duration of the Test.*—For tests made to ascertain either the maximum economy or the maximum capacity of a boiler, irrespective of the particular class of service for which it is regularly used, the duration should be at least ten hours of continuous running. If the rate of combustion exceeds 25 pounds of coal per square foot of grate-surface per hour, it may be stopped when a total of 250 pounds of coal has been burned per square foot of grate.

IX. *Starting and Stopping a Test.*—The conditions of the boiler and furnace in all respects should be, as nearly as possible, the same at the end as at the beginning of the test. The steam-pressure should be the same; the water-level the same; the fire upon the grates should be the same in quantity and condition; and the walls, flues, etc., should be of the same temperature. Two methods of obtaining the desired equality of conditions of the fire may be used, viz., those which were called in the Code of 1885 “the standard method” and “the alternate method,” the latter being employed where it is inconvenient to make use of the standard method.\*

X. *Standard Method of Starting and Stopping a Test.*—Steam being raised to the working pressure, remove rapidly all the fire from the grate, close the damper, clean the ash-pit, and as quickly as possible start a new fire with weighed wood and coal, noting the time and the water-level † while the water is in a quiescent state, just before lighting the fire.

At the end of the test remove the whole fire, which has been burned low, clean the grates and ash-pit, and note the water-level when the water is in a quiescent state, and record the time of hauling the fire. The water-level should be as nearly as possible the same as at the beginning of the test. If it is not the same, a correction should be made by computation, and not by operating the pump after the test is completed.

XI. *Alternate Method of Starting and Stopping a Test.*—The boiler being thoroughly heated by a preliminary run, the fires are to be burned low and well cleaned. Note the amount of coal left on the grate as nearly as it can be estimated; note the pressure of steam and the water-level. Note the time, and record it as the starting-time. Fresh coal which has been weighed should now be fired. The ash-pits should be thoroughly cleaned at once after starting. Before the end of the test the fires should be burned low, just as before the start, and the fires cleaned in such a manner as to leave a bed of coal on the grates of the same depth, and in the same condition, as at the start. When this stage is reached, note the time and record it as the stopping-time. The water-level and steam-pressures should previously be brought as nearly as possible to the same point as at the start. If the water-level is not the same as at the start, a correction should be made by computation, and not by operating the pump after the test is completed.

XII. *Uniformity of Conditions.*—In all trials made to ascertain maximum economy or capacity the conditions should be maintained uniformly constant. Arrangements should be made to dispose of the steam so that the rate of evaporation may be kept the same from beginning to end.

XIII. *Keeping the Records.*—Take note of every event connected with the progress of the trial, however unimportant it may appear. Record the time of every occurrence and the time of taking every weight and every observation.

The coal should be weighed and delivered to the fireman in equal proportions, each sufficient for not more than one hour's run, and a fresh portion

\*The Committee concludes that it is best to retain the designations “standard” and “alternate,” since they have become widely known and established in the minds of engineers and in the reprints in the Code of 1885. Many engineers prefer the “alternate” to the “standard” method on account of its being less liable to error due to cooling of the boiler at the beginning and end of a test.

†The gauge-glass should not be blown out within an hour before the water-level is taken at the beginning and end of a test, otherwise an error in the reading of the water-level may be caused by a change in the temperature and density to the water in the pipe leading from the bottom of the glass into the boiler.

should not be delivered until the previous one has all been fired. The time required to consume each portion should be noted, the time being recorded at the instant of firing the last of each portion. It is desirable that at the same time the amount of water fed into the boiler should be accurately noted and recorded, including the height of the water in the boiler, and the average pressure of steam and temperature of feed during the time. By thus recording the amount of water evaporated by successive portions of coal, the test may be divided into several periods if desired, and the degree of uniformity of combustion, evaporation, and economy analyzed for each period. In addition to these records of the coal and the feed-water, half-hourly observations should be made of the temperature of the feed-water, of the flue-gases, of the external air in the boiler-room, of the temperature of the furnace when a furnace-pyrometer is used, also of the pressure of steam, and of the readings of the instruments for determining the moisture in the steam. A log should be kept on properly prepared blanks containing columns for record of the various observations.

XIV. *Quality of Steam.*—The percentage of moisture in the steam should be determined by the use of either a throttling or a separating steam-calorimeter. The sampling-nozzle should be placed in the vertical steam-pipe rising from the boiler. It should be made of  $\frac{1}{2}$ -inch pipe, and should extend across the diameter of the steam-pipe to within half an inch of the opposite side, being closed at the end and perforated with not less than twenty  $\frac{1}{8}$ -inch holes equally distributed along and around its cylindrical surface, but none of these holes should be nearer than  $\frac{1}{2}$  inch to the inner side of the steam-pipe. The calorimeter and the pipe leading to it should be well covered with felting. Whenever the indications of the throttling or separating calorimeter show that the percentage of moisture is irregular, or occasionally in excess of three per cent., the results should be checked by a steam-separator placed in the steam-pipe as close to the boiler as convenient, with a calorimeter in the steam-pipe just beyond the outlet from the separator. The drip from the separator should be caught and weighed, and the percentage of moisture computed therefrom added to that shown by the calorimeter.

Superheating should be determined by means of a thermometer placed in a mercury-well inserted in the steam-pipe. The degree of superheating should be taken as the difference between the reading of the thermometer for superheated steam and the readings of the same thermometer for saturated steam at the same pressure as determined by a special experiment, and not by reference to steam-tables.

XV. *Sampling the Coal and Determining its Moisture.*—As each barrow-load or fresh portion of coal is taken from the coal-pile, a representative shovelful is selected from it and placed in a barrel or box in a cool place and kept until the end of the trial. The samples are then mixed and broken into pieces not exceeding one inch in diameter, and reduced by the process of repeated quartering and crushing until a final sample weighing about five pounds is obtained, and the size of the larger pieces is such that they will pass through a sieve with  $\frac{1}{4}$ -inch meshes. From this sample two one-quart, air-tight glass preserving-jars, or other air-tight vessels which will prevent the escape of moisture from the sample, are to be promptly filled, and these samples are to be kept for subsequent determinations of moisture and of heating value and for chemical analyses. During the process of quartering, when the sample has been reduced to about 100 pounds, a quarter to a half of it may be taken for an approximate determination of moisture. This may be made by placing it in a shallow iron pan, not over three inches deep, carefully weighing it, and setting the pan in the hottest place that can be found on the brickwork of the boiler-setting or flues, keeping it there for at least 12 hours, and then weighing it. The determination of moisture thus made is believed to be approximately accurate for anthracite and semi-bituminous coals, and also for Pittsburg or Youghiogheny coal; but it cannot be relied upon for coals mined west of Pittsburg, or for other coals containing inherent moisture. For these latter coals it is important that a more accurate method be adopted. The method recommended by the Committee for all accurate tests, whatever the character of the coal, is described as follows:

Take one of the samples contained in the glass jars, and subject it to a thorough air-drying, by spreading it in a thin layer and exposing it for several hours to the atmosphere of a warm room, weighing it before and after, thereby determining the quantity of surface moisture it contains.

Then crush the whole of it by running it through an ordinary coffee-mill adjusted so as to produce somewhat coarse grains (less than  $\frac{1}{8}$  inch), thoroughly mix the crushed sample, select from it a portion of from 10 to 50 grams, weigh it in a balance which will easily show a variation as small as 1 part in 1000, and dry it in an air- or sand-bath at a temperature between 240 and 280 degrees Fahr. for one hour. Weigh it and record the loss, then heat and weigh it again repeatedly, at intervals of an hour or less, until the minimum weight has been reached and the weight begins to increase by oxidation of a portion of the coal. The difference between the original and the minimum weight is taken as the moisture in the air-dried coal. This moisture test should preferably be made on duplicate samples, and the results should agree within 0.3 to 0.4 of one per cent., the mean of the two determinations being taken as the correct result. The sum of the percentage of moisture thus found and the percentage of surface moisture previously determined is the total moisture.

XVI. *Treatment of Ashes and Refuse.*—The ashes and refuse are to be weighed in a dry state. If it is found desirable to show the principal characteristics of the ash, a sample should be subjected to a proximate analysis and the actual amount of incombustible material determined. For elaborate trials a complete analysis of the ash and refuse should be made.

XVII. *Calorific Tests and Analysis of Coal.*—The quality of the fuel should be determined either by heat test or by analysis, or by both.

The rational method of determining the total heat of combustion is to burn the sample of coal in an atmosphere of oxygen gas, the coal to be sampled as directed in Article XV of this code.

The chemical analysis of the coal should be made only by an expert chemist. The total heat of combustion computed from the results of the ultimate analysis may be obtained by the use of Dulong's formula (with constants modified by recent determinations), viz.,

$$14,600 C + 62,000 \left( H - \frac{O}{8} \right) + 4000 S,$$

in which C, H, O, and S refer to the proportions of carbon, hydrogen, oxygen, and sulphur respectively, as determined by the ultimate analysis.\*

It is desirable that a proximate analysis should be made, thereby determining the relative proportions of volatile matter and fixed carbon. These proportions furnish an indication of the leading characteristics of the fuel, and serve to fix the class to which it belongs.

XVIII. *Analysis of Flue-gases.*—The analysis of the flue-gases is an especially valuable method of determining the relative value of different methods of firing or of different kinds of furnaces. In making these analyses great care should be taken to procure average samples, since the composition is apt to vary at different points of the flue. The composition is also apt to vary from minute to minute, and for this reason the drawings of gas should last a considerable period of time. Where complete determinations are desired, the analyses should be intrusted to an expert chemist. For approximate determinations the Orsat or the Hempel apparatus may be used by the engineer.

For the continuous indication of the amount of carbonic acid present in the flue-gases an instrument may be employed which shows the weight of CO<sub>2</sub> in the sample of gas passing through it.

XIX. *Smoke Observations.*—It is desirable to have a uniform system of determining and recording the quantity of smoke produced where bituminous coal is used. The system commonly employed is to express the degree of smokiness by means of percentages dependent upon the judgment of the observer. The actual measurement of a sample of soot and smoke by some form of meter is to be preferred.

XX. *Miscellaneous.*—In tests for purposes of scientific research, in which the determination of all the variables entering into the test is desired, certain observations should be made which are in general unnecessary for ordinary tests. As these determinations are rarely undertaken, it is not deemed advisable to give directions for making them.

XXI. *Calculations of Efficiency.*—Two methods of defining and calculating the efficiency of a boiler are recommended. They are:

\* Favre and Silbermann give 14,544 B.T.U. per pound carbon; Berthelot, 14,647 B.T.U. Favre and Silbermann give 62,032 B.T.U. per pound hydrogen; Thomsen, 61,816 B.T.U.

1. Efficiency of the boiler =  $\frac{\text{Heat absorbed per lb. combustible}}{\text{Calorific value of 1 lb. combustible}}$ .

2. Efficiency of the boiler and grate =  $\frac{\text{Heat absorbed per lb. coal}}{\text{Calorific value of 1 lb. coal}}$ .

The first of these is sometimes called the efficiency based on combustible, and the second the efficiency based on coal. The first is recommended as a standard of comparison for all tests, and this is the one which is understood to be referred to when the word "efficiency" alone is used without qualification. The second, however, should be included in a report of a test, together with the first, whenever the object of the test is to determine the efficiency of the boiler and furnace together with the grate (or mechanical stoker), or to compare different furnaces, grates, fuels, or methods of firing.

The heat absorbed per pound of combustible (or per pound coal) is to be calculated by multiplying the equivalent evaporation from and at 212 degrees per pound combustible (or coal) by 965.7.

XXII. *The Heat Balance.*—An approximate "heat balance," may be included in the report of a test when analyses of the fuel and of the chimney-gases have been made. It should be reported in the following form:

HEAT BALANCE, OR DISTRIBUTION OF THE HEATING VALUE OF THE COMBUSTIBLE.

Total Heat Value of 1 lb. of Combustible..... B. T. U.

	B. T. U.	Per Cent.
1. Heat absorbed by the boiler = evaporation from and at 212 degrees per pound of combustible $\times 965.7$ .....		
2. Loss due to moisture in coal = per cent of moisture referred to combustible $\div 100 \times [(212 - t) + 966 + 0.48(T - 212)]$ ( $t$ = temperature of air in the boiler-room, $T$ = that of the flue-gases).....		
3. Loss due to moisture formed by the burning of hydrogen = per cent of hydrogen to combustible $\div 100 \times 9 \times [(212 - t) + 966 + 0.48(T - 212)]$ .....		
4.* Loss due to heat carried away in the dry chimney-gases = weight of gas per pound of combustible $\times 0.24 \times (T - t)$ .....		
5.† Loss due to incomplete combustion of carbon = $\frac{\text{CO}}{\text{CO}_2 + \text{CO}} \times \frac{\text{per cent. C in combustible}}{100} \times 10,150$ ....		
6. Loss due to unconsumed hydrogen and hydrocarbons, to heating the moisture in the air, to radiation, and unaccounted for. (Some of these losses may be separately itemized if data are obtained from which they may be calculated).....		
Totals .....		100.00

\* The weight of gas per pound of carbon burned may be calculated from the gas analyses as follows:

Dry gas per pound carbon =  $\frac{11\text{CO}_2 + 8\text{O} + 7(\text{CO} + \text{N})}{3(\text{CO}_2 + \text{CO})}$ , in which  $\text{CO}_2$ ,  $\text{CO}$ ,

$\text{O}$ , and  $\text{N}$  are the percentages by volume of the several gases. As the sampling and analyses of the gases in the present state of the art are liable to considerable errors, the result of this calculation is usually only an approximate one. The heat balance itself is also only approximate for this reason, as well as for the fact that it is not possible to determine accurately the percentage of unburned hydrogen or hydrocarbons in the flue-gases.

The weight of dry gas per pound of combustible is found by multiplying the dry gas per pound of carbon by the percentage of carbon in the combustible, and dividing by 100.

†  $\text{CO}_2$  and  $\text{CO}$  are respectively the percentage by volume of carbonic acid and carbonic oxide in the flue-gases. The quantity 10,150 = number of heat-units generated by burning to carbonic acid one pound of carbon contained in carbonic oxide.

XXIII. *Report of the Trial.*—The data and results should be reported in the manner given in either one of the two following tables [only the “Short Form” of table is given here], omitting lines where the tests have not been made as elaborately as provided for in such tables. Additional lines may be added for data relating to the specific object of the test. The Short Form of Report, Table No. 2, is recommended for commercial tests and as a convenient form of abridging the longer form for publication when saving of space is desirable. For elaborate trials it is recommended that the full log of the trial be shown graphically, by means of a chart.

TABLE NO. 2.

DATA AND RESULTS OF EVAPORATIVE TEST,

Arranged in accordance with the Short Form advised by the Boiler Test Committee of the American Society of Mechanical Engineers. Code of 1899.

Made by.....on.....boiler, at.....to determine.....  
 Kind of fuel.....  
 Kind of furnace.....

Method of starting and stopping the test (“stand-ard” or “alternate,” Arts. X and XI, Code).....

15. Equivalent evaporation per hour from and at 212 degrees per square foot of water-heating sur-face ¶.....	“	

\* Including equivalent of wood used in lighting the fire, not including unburnt coal withdrawn from furnace at times of cleaning and at end of test. One pound of wood is taken to be equal to 0.4 pound of coal, or, in case greater accuracy is desired, as having a heat value equivalent to the evaporation of 6 pounds of water from and at 212 degrees per pound. (6 × 965.7 = 5794 B. T. U.) The term “as fired” means in its actual condition, including moisture.

† This is the total moisture in the coal as found by drying it artificially, as described in Art. XV of Code.

‡ Corrected for inequality of water-level and of steam-pressure at beginning and end of test.

§ Factor of evaporation =  $\frac{H - h}{965.7}$ , in which *H* and *h* are respectively the total heat in steam of the average observed pressure, and in water of the average observed temperature of the feed.

¶ The symbol “U. E.,” meaning “units of evaporation,” may be con-

COST OF EVAPORATION.	
32. Cost of coal per ton of — lbs. delivered in boiler-room.....	¢
33. Cost of coal required for evaporating 1000 pounds of water from and at 212 degrees. ....	\$

veniently substituted for the expression "Equivalent water evaporated into dry steam from and at 212 degrees," its definition being given in a foot-note.

¶ Held to be the equivalent of 30 lbs. of water evaporated from 100 degrees Fahr. into dry steam at 70 lbs. gauge-pressure.

\*\* In all cases where the word "combustible" is used, it means the coal without moisture and ash, but including all other constituents. It is the same as what is called in Europe "coal-dry and free from ash."

**Factors of Evaporation.**—The table on the following pages was originally published by the author in *Trans. A. S. M. E.*, vol. vi., 1884, under the title, *Tables for Facilitating Calculations of Boiler-tests*. The table gives the factors for every 3° of temperature of feed-water from 32° to 212° F., and for every two pounds pressure of steam within the limits of ordinary working steam-pressures.

The difference in the factor corresponding to a difference of 3° temperature of feed is always either .0031 or .0032. For interpolation to find a factor for a feed-water temperature between 32° and 212°, not given in the table, take the factor for the nearest temperature and add or subtract, as the case may be, .0010 if the difference is .0031, and .0011 if the difference is .0032. As in nearly all cases a factor of evaporation to three decimal places is accurate enough, any error which may be made in the fourth decimal place by interpolation is of no practical importance.

The tables used in calculating these factors of evaporation are those given in Charles T. Porter's *Treatise on the Richards' Steam-engine Indicator*.

The formula is  $\text{Factor} = \frac{H - h}{965.7}$ , in which  $H$  is the total heat of steam at the observed pressure, and  $h$  the total heat of feed-water of the observed temperature.

## STRENGTH OF STEAM-BOILERS. VARIOUS RULES FOR CONSTRUCTION.

There is a great lack of uniformity in the rules prescribed by different writers and by legislation governing the construction of steam-boilers. In the United States, boilers for merchant vessels must be constructed according to the rules and regulations prescribed by the Board of Supervising Inspectors of Steam Vessels; in the U. S. Navy, according to rules of the Navy Department, and in some cases according to special acts of Congress. On land, in some places, as in Philadelphia, the construction of boilers is governed by local laws; but generally there are no laws upon the subject, and boilers are constructed according to the idea of individual engineers and boiler-makers. In Europe the construction is generally regulated by stringent inspection laws. The rules of the U. S. Supervising Inspectors of Steam-vessels, the British Lloyd's and Board of Trade, the French Bureau Veritas, and the German Lloyd's are ably reviewed in a paper by Nelson Foley, M. Inst. Naval Architects, etc., read at the Chicago Engineering Congress, Division of Marine and Naval Engineering. From this paper the following notes are taken, chiefly with reference to the U. S. and British rules: (*Abbreviations*.—T. S., for tensile strength; El., elongation; Contr., contraction of area.)

**Hydraulic Tests.**—*Board of Trade, Lloyd's, and Bureau Veritas.*—Twice the working pressure.

*United States Statutes.*—One and a half times the working pressure.

Mr. Foley proposes that the proof pressure should be  $1\frac{1}{2}$  times the working pressure + one atmosphere.

**Established Nominal Factors of Safety.**—*Board of Trade.*—4.5 for a boiler of moderate length and of the best construction and workmanship.

*Lloyd's.*—Not very apparent, but appears to lie between 4 and 5.

*United States Statutes.*—Indefinite, because the strength of the joint is not considered, except by the broad distinction between single and double riveting.

*Bureau Veritas:* 4.4.

*German Lloyd's:* 5 to 4.65, according to the thickness of the plates.

**Material for Riveting.**—*Board of Trade.*—Tensile strength of rivet bars between 26 and 30 tons, el. in 10" not less than 25%, and contr. of area not less than 50%.

*Lloyd's.*—T. S., 26 to 30 tons; el. not less than 20% in 8". The material must stand bending to a curve, the inner radius of which is not greater than  $1\frac{1}{2}$  times the thickness of the plate, after having been uniformly heated to a low cherry-red, and quenched in water at 82° F.

*United States Statutes.*—No special provision.

**Rules Connected with Riveting.**—*Board of Trade.*—The shearing resistance of the rivet steel to be taken at 23 tons per square inch, 5 to be used for the factor of safety independently of any addition to this factor for the plating. Rivets in double shear to have only 1.75 times the single section taken in the calculation instead of 2. The diameter must not be less than the thickness of the plate and the pitch never greater than  $8\frac{1}{2}$ ". The thickness of double butt-straps (each) not to be less than  $\frac{5}{8}$  the thickness of the plate; single butt-straps not less than  $\frac{9}{8}$ .

Distance from centre of rivet to edge of hole = diameter of rivet  $\times 1\frac{1}{2}$ .

Distance between rows of rivets

$$= 2 \times \text{diam. of rivet or } = [(\text{diam.} \times 4) + 1] + 2, \text{ if chain, and} \\ = \frac{\sqrt{[(\text{pitch} \times 11) + (\text{diam.} \times 4)] \times (\text{pitch} + \text{diam.} \times 4)}}{10} \text{ if zigzag.}$$

Diagonal pitch = (pitch  $\times 6$  + diam.  $\times 4$ ) + 10.

*Lloyd's.*—Rivets in double shear to have only 1.75 times the single section taken in the calculation instead of 2. The shearing strength of rivet steel to be taken at 85% of the T. S. of the material of shell plates. In any case where the strength of the longitudinal joint is satisfactorily shown by experiment to be greater than given by the formula, the actual strength may be taken in the calculation.

*United States Statutes.*—No rules.

**Material for Cylindrical Shells Subject to Internal Pressure.**—*Board of Trade.*—T. S. between 27 and 32 tons. In the normal condition, el. not less than 18% in 10", but should be about 25%; if annealed, not

less than 20%. Strips 2" wide should stand bending until the sides are parallel at a distance from each other of not more than three times the plate's thickness.

*Lloyd's*.—T. S. between the limits of 26 and 30 tons per square inch. El. not less than 20% in 8". Test strips heated to a low cherry-red and plunged into water at 82° F. must stand bending to a curve, the inner radius of which is not greater than 1½ times the plate's thickness.

*U. S. Statutes*.—Plates of ½" thick and under shall show a contr. of not less than 50%; when over ½" and up to ¾", not less than 45%; when over ¾", not less than 40%.

Mr. Foley's comments: The Board of Trade rules seem to indicate a steel of too high T. S. when a lower and more ductile one can be got: the lower tensile limit should be reduced, and the bending test might with advantage be made after tempering, and made to a smaller radius. Lloyd's rule for quality seems more satisfactory, but the temper test is not severe. The United States Statutes are not sufficiently stringent to insure an entirely satisfactory material.

Mr. Foley suggests a material which would meet the following: 25 tons lower limit in tension; 25% in 8" minimum elongation; radius for bending test after tempering = the plate's thickness.

**Shell-plate Formulæ.**—*Board of Trade*:  $P = \frac{T \times B \times t \times 2}{D \times F}$ .

$D$  = diameter of boiler in inches;

$P$  = working-pressure in lbs. per square inch;

$t$  = thickness in inches;

$B$  = percentage of strength of joint compared to solid plate;

$T$  = tensile strength allowed for the material in lbs. per square inch;

$F$  = a factor of safety, being 4.5, with certain additions depending on method of construction.

*Lloyd's*:  $P = \frac{C \times (t - 2) \times B}{D}$ .

$t$  = thickness of plate in sixteenths;  $B$  and  $D$  as before;  $C$  = a constant depending on the kind of joint.

When longitudinal seams have double butt-straps,  $C = 20$ . When longitudinal seams have double butt-straps of unequal width, only covering on one side the reduced section of plate at the outer line of rivets,  $C = 19.5$ .

When the longitudinal seams are lap-jointed,  $C = 18.5$ .

*U. S. Statutes*.—Using same notation as for Board of Trade,

$P = \frac{t \times 2 \times T}{D \times 6}$  for single-riveting; add 20% for double-riveting;

where  $T$  is the lowest T. S. stamped on any plate.

Mr. Foley criticises the rule of the United States Statutes as follows: The rule ignores the riveting, except that it distinguishes between single and double, giving the latter 20% advantage; the circumferential riveting or class of seam is altogether ignored. The rule takes no account of workmanship or method adopted of constructing the joints. The factor, one sixth, simply covers the actual nominal factor of safety as well as the loss of strength at the joint, no matter what its percentage; we may therefore dismiss it as unsatisfactory.

**Rules for Flat Plates.**—*Board of Trade*;  $P = \frac{C(t + 1)^2}{S - 6}$ .

$P$  = working-pressure in lbs. per square inch;

$S$  = surface supported in square inches;

$t$  = thickness in sixteenths of an inch;

$C$  = a constant as per following table:

$C = 125$  for plates not exposed to heat or flame, the stays fitted with nuts and washers, the latter at least three times the diameter of the stay and ¾ the thickness of the plate;

$C = 187.5$  for the same condition, but the washers ¾ the pitch of stays in diameter, and thickness not less than plate;

$C = 200$  for the same condition, but doubling plates in place of washers, the width of which is ¾ the pitch and thickness the same as the plate;

$C = 112.5$  for the same condition, but the stays with nuts only;

$C = 75$  when exposed to impact of heat or flame and steam in contact with the plates, and the stays fitted with nuts and washers three times the diameter of the stay and ¾ the plate's thickness;

- $C = 67.5$  for the same condition, but stays fitted with nuts only;  
 $C = 100$  when exposed to heat or flame, and water in contact with the plates,  
 and stays screwed into the plates and fitted with nuts;  
 $C = 66$  for the same condition, but stays with riveted heads.

*U. S. Statutes.*—Using same notation as for Board of Trade.  $P = \frac{C \times t^2}{p^2}$ ,  
 where  $p$  = greatest pitch in inches,  $P$  and  $t$  as above;

- $C = 112$  for plates  $7/16''$  thick and under, fitted with screw stay-bolts  
 riveted over, screw stay-bolts and nuts, or plain bolt fitted  
 with single nut and socket, or riveted head and socket;  
 $C = 120$  for plates above  $7/16''$ , under the same conditions;  
 $C = 140$  for flat surfaces where the stays are fitted with nuts inside  
 and outside;  
 $C = 200$  for flat surfaces under the same condition, but with the addi-  
 tion of a washer riveted to the plate at least  $1/2$  plate's thick-  
 ness, and of a diameter equal to  $7/8$  of the pitch of the stay-bolts.

**N.B.**—Plates fitted with double angle-irons and riveted to plate, with leaf  
 at least  $2/3$  the thickness of plate and depth at least  $1/4$  of pitch, would be  
 allowed the same pressure as determined by formula for plate with washer  
 riveted on.

**N.B.**—No brace or stay-bolt used in marine boilers to have a greater pitch  
 than  $10 1/2''$  on fire-boxes and back connections.

Certain experiments were carried out by the Board of Trade which showed  
 that the resistance to bulging does not vary as the square of the plate's  
 thickness. There seems also good reason to believe that it is not inversely  
 as the square of the greatest pitch. Bearing in mind, says Mr. Foley, that  
 mathematicians have signally failed to give us true theoretical foundations  
 for calculating the resistance of bodies subject to the simplest forms of  
 stresses, we therefore cannot expect much from their assistance in the  
 matter of flat plates.

The Board of Trade rules for flat surfaces, being based on actual experi-  
 ment, are especially worthy of respect; sound judgment appears also to  
 have been used in framing them.

**Furnace Formulæ.**—BOARD OF TRADE.—*Long Furnaces.*—

$P = \frac{C \times t^2}{(L + 1) \times D}$ , but not where  $L$  is shorter than  $(11.5t - 1)$ , at which length  
 the rule for short furnaces comes into play.

$P$  = working-pressure in pounds per square inch;  $t$  = thickness in inches;  
 $D$  = outside diameter in inches;  $L$  = length of furnace in feet up to 10 ft.;

- $C$  = a constant, as per following table, for drilled holes:  
 $C = 99,000$  for welded or butt-jointed with single straps, double-  
 riveted;  
 $C = 88,000$  for butts with single straps, single-riveted;  
 $C = 99,000$  for butts with double straps, single-riveted.

Provided always that the pressure so found does not exceed that given by  
 the following formulæ, which apply also to short furnaces:

$$P = \frac{C \times t}{D} \text{ for all the patent furnaces named;}$$

$$P = \frac{C \times t}{3 \times D} \left( 5 - \frac{L \times 12}{67.5 \times t} \right) \text{ when with Adamson rings.}$$

- $C = 8,800$  for plain furnaces;  
 $C = 14,000$  for Fox; minimum thickness  $5/16''$ , greatest  $5/8''$ ; plain part  
 not to exceed  $6''$  in length;  
 $C = 13,500$  for Morison; minimum thickness  $5/16''$ , greatest  $5/8''$ ; plain  
 part not to exceed  $6''$  in length;  
 $C = 14,000$  for Purves-Brown; limits of thickness  $7/16''$  and  $5/8''$ ; plain  
 part  $9''$  in length;  
 $C = 8,800$  for Adamson rings; radius of flange next fire  $1 1/2''$ .

**U. S. STATUTES.**—*Long Furnaces.*—Same notation.

$$P = \frac{89,600 \times t^2}{L \times D}, \text{ but } L \text{ not to exceed } 8 \text{ ft.}$$

**N.B.**—If rings of wrought iron are fitted and riveted on properly around  
 and to the flue in such a manner that the tensile stress on the rivets shall

not exceed 6000 lbs. per sq. in., the distance between the rings shall be taken as the length of the flue in the formulæ.

*Short Furnaces, Plain and Patent.*— $P$ , as before, when not 8 ft.  

$$\text{long} = \frac{89,600 \times t^2}{L \times D};$$

$$P = \frac{t \times C}{D} \text{ when}$$

$C = 14,000$  for Fox corrugations where  $D =$  mean diameter;

$C = 14,000$  for Purves-Brown where  $D =$  diameter of flue;

$C = 5677$  for plain flues over 16" diameter and less than 40", when not over 3 ft. lengths.

Mr. Foley comments on the rules for long furnaces as follows: The Board of Trade general formula, where the length is a factor, has a very limited range indeed, viz., 10 ft. as the extreme length, and 135 thicknesses — 12", as the short limit. The original formula,  $P = \frac{C \times t^2}{L \times D}$ , is that of Sir W.

Fairbairn, and was, I believe, never intended by him to apply to short furnaces. On the very face of it, it is apparent, on the other hand, that if it is true for moderately long furnaces, it cannot be so for very long ones. We are therefore driven to the conclusion that any formula which includes simple  $L$  as a factor must be founded on a wrong basis.

With Mr. Traill's form of the formula, namely, substituting  $(L + 1)$  for  $L$ , the results appear sufficiently satisfactory for practical purposes, and indeed, as far as can be judged, tally with the results obtained from experiment as nearly as could be expected. The experiments to which I refer were six in number, and of great variety of length to diameter; the actual factors of safety ranged from 4.4 to 6.2, the mean being 4.78, or practically 5. It seems to me, therefore, that, within the limits prescribed, the Board of Trade formula may be accepted as suitable for our requirements.

The United States Statutes give Fairbairn's rule pure and simple, except that the extreme limit of length to which it applies is fixed at 8 feet. As far as can be seen, no limit for the shortest length is prescribed, but the rules to me are by no means clear, flues and furnaces being mixed or not well distinguished.

**Material for Stays.**—The qualities of material prescribed are as follows:

*Board of Trade.*—The tensile strength to lie between the limits of 27 and 32 tons per square inch, and to have an elongation of not less than 20% in 16". Steel stays which have been welded or worked in the fire should not be used.

*Lloyd's.*—26 to 30 ton steel, with elongation not less than 20% in 8".

*U. S. Statutes.*—The only condition is that the reduction of area must not be less than 40% if the test bar is over  $\frac{3}{4}$ " diameter.

**Loads allowed on Stays.**—*Board of Trade.*—9000 lbs. per square inch is allowed on the net section, provided the tensile strength ranges from 27 to 32 tons. Steel stays are not to be welded or worked in the fire.

*Lloyd's.*—For screwed and other stays, not exceeding  $1\frac{1}{8}$ " diameter effective, 8000 lbs. per square inch is allowed; for stays above  $1\frac{1}{2}$ ", 9000 lbs. No stays are to be welded.

*U. S. Statutes.*—Braces and stays shall not be subjected to a greater stress than 6000 lbs. per square inch.

[Rankine, S. E., p. 459, says: "The iron of the stays ought not to be exposed to a greater working tension than 3000 lbs. on the square inch, in order to provide against their being weakened by corrosion. This amounts to making the factor of safety for the working pressure about 20." It is evident, however, that an allowance in the factor of safety for corrosion may reasonably be decreased with increase of diameter. W. K.]

**Girders.**—*Board of Trade.*  $P = \frac{C \times d^2 \times t}{(W - p)D \times L}$ .  $P =$  working pressure in lbs. per sq. in.;  $W =$  width of flame-box in inches;  $L =$  length of girder in inches;  $p =$  pitch of bolts in inches;  $D =$  distance between girders from centre to centre in inches;  $d =$  depth of girder in inches;  $t =$  thickness of sum of same in inches;  $C =$  a constant = 6600 for 1 bolt, 9900 for 2 or 3 bolts, and 11,220 for 4 bolts.

*Lloyd's.*—The same formula and constants, except that  $C = 11,000$  for 4 or 5 bolts, 11,550 for 6 or 7, and 11,880 for 8 or more.

*U. S. Statutes.*—The matter appears to be left to the designers.

**Tube-Plates.**—*Board of Trade.*  $P = \frac{t(D - d) \times 20,000}{W \times D}$ .  $D =$  least

horizontal distance between centres of tubes in inches;  $d =$  inside diameter of ordinary tubes;  $t =$  thickness of tube-plate in inches;  $W =$  extreme width of combustion-box in inches from front tube-plate to back of fire-box, or distance between combustion-box tube-plates when the boiler is double-ended and the box common to both ends.

The crushing stress on tube-plates caused by the pressure on the flame-box top is to be limited to 10,000 lbs. per square inch.

**Material for Tubes.**—Mr. Foley proposes the following: If iron, the quality to be such as to give at least 22 tons per square inch as the minimum tensile strength, with an elongation of not less than 15% in 8". If steel, the elongation to be not less than 26% in 8" for the material before being rolled into strips; and after tempering, the test bar to stand completely closing together. Provided the steel welds well, there does not seem to be any objection in providing tensile limits.

The ends should be annealed after manufacture, and stay-tube ends should be annealed before screwing.

**Holding-power of Boiler-tubes.**—Experiments made in Washington Navy Yard show that with 2½ in. brass tubes in no case was the holding-power less, roughly speaking, than 6000 lbs., while the average was upwards of 20,000 lbs. It was further shown that with these tubes nuts were superfluous, quite as good results being obtained with tubes simply expanded into the tube-plate and fitted with a ferrule. When nuts were fitted it was shown that they drew off without injuring the threads.

In Messrs. Yarrow's experiments on iron and steel tubes of 2" to 2¼" diameter the first 5 tubes gave way on an average of 23,740 lbs., which would appear to be about ¾ the ultimate strength of the tubes themselves. In all these cases the hole through the tube-plate was parallel with a sharp edge to it, and a ferrule was driven into the tube.

Tests of the next 5 tubes were made under the same conditions as the first 5, with the exception that in this case the ferrule was omitted, the tubes being simply expanded into the plates. The mean pull required was 15,270 lbs., or considerably less than half the ultimate strength of the tubes.

*Effect of beading the tubes,* the holes through the plate being parallel and ferrules omitted. The mean of the first 3, which are tubes of the same kind, gives 26,876 lbs. as their holding-power, under these conditions, as compared with 23,740 lbs. for the tubes fitted with ferrules only. This high figure is, however, mainly due to an exceptional case where the holding-power is greater than the average strength of the tubes themselves.

It is disadvantageous to cone the hole through the tube-plate unless its sharp edge is removed, as the results are much worse than those obtained with parallel holes, the mean pull being but 16,031 lbs., the experiments being made with tubes expanded and ferruled but not beaded over.

In experiments on tubes expanded into tapered holes, beaded over and fitted with ferrules, the net result is that the holding-power is, for the size experimented on, about ¾ of the tensile strength of the tube, the mean pull being 28,797 lbs.

With tubes expanded into tapered holes and simply beaded over, better results were obtained than with ferrules; in these cases, however, the sharp edge of the hole was rounded off, which appears in general to have a good effect.

In one particular the experiments are incomplete, as it is impossible to reproduce on a machine the racking the tubes get by the expansion of a boiler as it is heated up and cooled down again, and it is quite possible, therefore, that the fastening giving the best results on the testing-machine may not prove so efficient in practice.

N.B.—It should be noted that the experiments were all made under the cold condition, so that reference should be made with caution, the circumstances in practice being very different, especially when there is scale on the tube-plates, or when the tube-plates are thick and subject to intense heat.

**Iron versus Steel Boiler-tubes.** (Foley.)—Mr. Blechynden prefers iron tubes to those of steel, but how far he would go in attributing the leaky-tube defect to the use of steel tubes we are not aware. It appears, however, that the results of his experiments would warrant him in going a considerable distance in this direction. The test consisted of heating and cooling two tubes, one of wrought iron and the other of steel. Both tubes were 2¾ in. in diameter and .16 in. thickness of metal. The tubes were

put in the same furnace, made red-hot, and then dipped in water. The length was gauged at a temperature of 46° F.

This operation was twice repeated, with results as follows :

	Steel.	Iron.
Original length.....	55.495 in.	55.495 in.
Heated to 186° F.; increase.....	.052 "	.048 "
Coefficient of expansion per degree F.....	.0000067	.0000062
Heated red-hot and dipped in water; decrease	.007 in.	.003 in.
Second heating and cooling, decrease.....	.031 in.	.004 in.
Third heating and cooling, decrease....	.017 in.	.006 in.
Total contraction ..	.055 in.	.013 in.

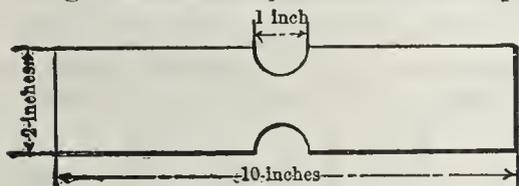

Mr. A. C. Kirk writes : That overheating of tube ends is the cause of the leakage of the tubes in boilers is proved by the fact that the ferrules at present used by the Admiralty prevent it. These act by shielding the tube ends from the action of the flame, and consequently reducing evaporation, and so allowing free access of the water to keep them cool.

Although many causes contribute, there seems no doubt that thick tube-plates must bear a share of causing the mischief.

### Rules for Construction of Boilers in Merchant Vessels in the United States.

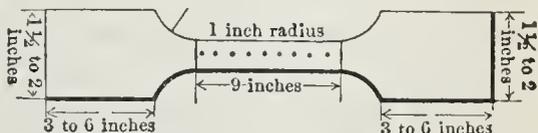

(Extracts from General Rules and Regulations of the Board of Supervising Inspectors of Steam-vessels (as amended 1898).)

**Tensile Strength of Plate.** (Section 3.)—To ascertain the tensile strength and other qualities of iron plate there shall be taken from each sheet to be used in shell or other parts of boiler which are subject to tensile strain a test piece prepared in form according to the following diagram, viz.: 10 inches in length, 2 inches in width, cut out in the centre in the manner indicated.

and other qualities of *steel plate*, there shall be taken from each sheet to be used in shell or other parts of boiler which are subject to tensile strain a test-piece prepared in form according to the following diagram:

The straight part in centre shall be 9 inches in length and 1 inch in width, marked with light prick-punch marks at distances 1 inch apart, as shown, spaced so as to give 8 inches in length.

The sample must show when tested an elongation of at least 25% in a length of 2 in. for thickness up to 1/4 in., inclusive; in a length of 4 in. for over 1/4 to 7/16, inclusive; in a length of 6 in., for all plates over 7/16 in. and under 1 1/4 in. thickness.

The reduction of area shall be the same as called for by the rules of the Board. No plate shall contain more than .06% of phosphorus and .04% of sulphur.

The samples shall also be capable of being bent to a curve, of which the inner radius is not greater than 1 1/2 times the thickness of the plates after having been heated uniformly to a low cherry-red and quenched in water of 82° F.

[Prior to 1894 the shape of test-piece for steel was the same as that for iron, viz., the grooved shape. This shape has been condemned by authorities on strength of materials for over twenty years. It always gives results which are too high, the error sometimes amounting to 25 per cent. See pages 242, 243, ante; also, Strength of Materials, W. Kent, Van N. Science Series No. 41, and Beardslee on Wrought-iron and Chain Cables.]

**Ductility.** (Section 6.)—To ascertain the ductility and other lawful qualities, iron of 45,000 lbs. tensile strength shall show a contraction of area of 15 per cent, and each additional 1000 lbs. tensile strength shall show 1 per cent additional contraction of area, up to and including 55,000 tensile strength. Iron of 55,000 tensile strength and upwards, showing 25 per cent reduction of area, shall be deemed to have the lawful ductility. All steel plate of 1/2 inch thickness and under shall show a contraction of area of not less than 50 per cent. Steel plate over 1/2 inch in thickness, up to 3/4 inch in

thickness, shall show a reduction of not less than 45 per cent. All steel plate over  $\frac{3}{4}$  inch thickness shall show a reduction of not less than 40 per cent.

**Bumped Heads of Boilers.** (Section 17 as amended 1894.)—*Pressure Allowed on Bumped Heads.*—Multiply the thickness of the plate by one sixth of the tensile strength, and divide by six tenths of the radius to which head is bumped, which will give the pressure per square inch of steam allowed.

*Pressure Allowable for Concaved Heads of Boilers.*—Multiply the pressure per square inch allowable for bumped heads attached to boilers or drums convexly, by the constant .6, and the product will give the pressure per square inch allowable in concaved heads.

**The pressure on unstayed flat-heads** on steam-drums or shells of boilers, when flanged and made of wrought iron or steel or of cast steel, shall be determined by the following rule:

The thickness of plate in inches multiplied by one sixth of its tensile strength in pounds, which product divided by the area of the head in square inches multiplied by 0.9 will give pressure per square inch allowed. The material used in the construction of flat-heads when tensile strength has not been officially determined shall be deemed to have a tensile strength of 45,000 lbs.

### Table of Pressures allowable on Steam-boilers made of Riveted Iron or Steel Plates.

(Abstract from a table published in Rules and Regulations of the U. S. Board of Supervising Inspectors of Steam-vessels.)

Plates  $\frac{1}{4}$  inch thick. For other thicknesses, multiply by the ratio of the thickness to  $\frac{1}{4}$  inch.

Diameter of Boiler, ins.	50,000 Tensile Strength.		55,000 Tensile Strength.		60,000 Tensile Strength.		65,000 Tensile Strength.		70,000 Tensile Strength.	
	Pressure.	20% Additional.

The figures under the columns headed "pressure" are for single-riveted boilers. Those under the columns headed "20% Additional" are for double-riveted.

#### U. S. RULE FOR ALLOWABLE PRESSURES.

The pressure of any dimension of boilers not found in the table annexed to these rules must be ascertained by the following rule:

Multiply one sixth of the lowest tensile strength found stamped on any plate in the cylindrical shell by the thickness (expressed in inches or parts of an inch) of the thinnest plate in the same cylindrical shell, and divide by the radius or half diameter (also expressed in inches), the quotient will be the pressure allowable per square inch of surface for single-riveting, to which add twenty per centum for double-riveting when all the rivet-holes in the shell of such boiler have been "fairly drilled" and no part of such hole has been punched.

The author desires to express his condemnation of the above rule, and of the tables derived from it, as giving too low a factor of safety. (See also criticism by Mr. Foley, page 701, ante.)

If  $P_b$  = bursting-pressure,  $t$  = thickness,  $T$  = tensile strength,  $c$  = coefficient of strength of riveted joint, that is, ratio of strength of the joint to that of the solid plate,  $d$  = diameter,  $P_b = \frac{2tTc}{d}$ , or if  $c$  be taken for double-riveting at 0.7, then  $P_b = \frac{1.4tT}{d}$ .

By the U. S. rule the allowable pressure  $P_a = \frac{1/6tT}{1/2d} \times 1.20 = \frac{0.4tT}{d}$ ; whence  $P_b = 3.5P_a$ ; that is, the factor of safety is only 3.5, provided the "tensile strength found stamped in the plate" is the real tensile strength of the material. But in the case of iron plates, since the stamped T.S. is obtained from a grooved specimen, it may be greatly in excess of the real T.S., which would make the factor of safety still lower. According to the table, a boiler 40 in. diam.,  $\frac{1}{4}$  in. thick, made of iron stamped 60,000 T.S., would be licensed to carry 150 lbs. pressure if double-riveted. If the real T.S. is only 50,000 lbs. the calculated bursting-strength would be

$$P = \frac{2tTc}{d} = \frac{2 \times 50,000 \times .25 \times .70}{40} = 437.5 \text{ lbs.,}$$

and the factor of safety only  $437.5 \div 150 = 2.91$

The author's formula for safe working-pressure of externally-fired boilers with longitudinal seams double-riveted, is  $P = \frac{14000t}{d}$ ;  $t = \frac{Pd}{14000}$ ;  $P$  = gauge-pressure in lbs. per sq. in.;  $t$  = thickness and  $d$  = diam. in inches.

This is derived from the formula  $P = \frac{2tTc}{fd}$ , taking  $c$  at 0.7 and  $f = 5$  for steel of 50,000 lbs. T.S., or 6 for 60,000 lbs. T.S.; the factor of safety being increased in the ratio of the T.S., since with the higher T.S. there is greater danger of cracking at the rivet-holes from the effect of punching and riveting and of expansion and contraction caused by variations of temperature. For external shells of internally-fired boilers, these shells not being exposed to the fire, with rivet-holes drilled or reamed after punching, a lower factor of safety and steel of a higher T.S. may be allowable.

If the T.S. is 60,000, a working pressure  $P = \frac{16000t}{d}$  would give a factor of safety of 5.25.

The following table gives safe working pressures for different diameters of shell and thicknesses of plate calculated from the author's formula.

**Safe Working Pressures in Cylindrical Shells of Boilers, Tanks, Pipes, etc., in Pounds per Square Inch.**

Longitudinal seams double-riveted.  
(Calculated from formula  $P = 14,000 \times \text{thickness} \div \text{diameter}$ .)

**Rules governing Inspection of Boilers in Philadelphia.**

In estimating the strength of the longitudinal seams in the cylindrical shells of boilers the inspector shall apply two formulæ, A and B :

- A,  $\left\{ \frac{\text{Pitch of rivets} - \text{diameter of holes punched to receive the rivets}}{\text{pitch of rivets}} = \right.$   
percentage of strength of the sheet at the seam.
- B,  $\left\{ \frac{\text{Area of hole filled by rivet} \times \text{No. of rows of rivets in seam} \times \text{shear-}}{\text{pitch of rivets} \times \text{thickness of sheet} \times \text{tensile strength of sheet}} = \right.$   
ing strength of rivet  
percentage of strength of the rivets in the seam.

Take the lowest of the percentages as found by formulæ A and B and apply that percentage as the "strength of the seam" in the following formula C, which determines the strength of the longitudinal seams:

- C,  $\left\{ \frac{\text{Thickness of sheet in parts of inch} \times \text{strength of seam as obtained}}{\text{internal radius of boiler in inches} \times 5 \text{ as a factor of safety}} = \right.$   
by formula A or B  $\times$  ultimate strength of iron stamped on plates  
safe working pressure.

**Flues and Tubes for Steam-boilers.**—(From Rules of U. S. Supervising Inspectors. Steam-pressures per square inch allowable on riveted and lap-welded flues made in sections. Extract from table in Rules of U. S. Supervising Inspectors.)

*T* = least thickness of material allowable, *D* = greatest diameter in inches, *P* = allowable pressure. For thickness greater than *T* with same diameter *P* is increased in the ratio of the thickness.

<i>D</i> = in.	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23
<i>T</i> = in.	.18	.20	.21	.21	.22	.22	.23	.24	.25	.26	.27	.28	.29	30	.31	.32	.33
<i>P</i> = lbs.	189	184	179	174	172	158	152	147	143	139	136	134	131	129	126	125	122
<i>D</i> = in.	24	25	26	27	28	29	30	31	32	33	34	35	36	37	38	39	40
<i>T</i> = in.	.34	.35	.36	.37	.38	.39	.40	.41	.42	.43	.44	.45	.46	.47	.48	.49	.50
<i>P</i> = lbs.	121	120	119	117	116	115	115	114	112	112	110	110	109	109	108	108	107

For diameters not over 10 inches the greatest length of section allowable is 5 feet; for diameters 10 to 23 inches, 3 feet; for diameters 23 to 40 inches, 30 inches. If lengths of sections are greater than these lengths, the allowable pressure is reduced proportionately.

The U. S. rule for corrugated flues, as amended in 1894, is as follows: Rule II, Section 14. The strength of all corrugated flues, when used for furnaces or steam chimneys (corrugation not less than 1 1/2 inches deep and not exceeding 8 inches from centres of corrugation), and provided that the plain parts at the ends do not exceed 6 inches in length, and the plates are not less than 5/16 inch thick, when new, corrugated, and practically true circles, to be calculated from the following formula:

$$\frac{14,000}{D} \times T = \text{pressure.}$$

*T* = thickness, in inches; *D* = mean diameter in inches.

**Ribbed Flues.**—The same formula is given for ribbed flues, with rib projections not less than 1 3/8 inches deep and not more than 9 inches apart.

**Flat Stayed Surfaces in Steam-boilers.**—Rule II., Section 6, of the rules of the U. S. Supervising Inspectors provides as follows:

No braces or stays hereafter employed in the construction of boilers shall be allowed a greater strain than 6000 lbs. per square inch of section.

Clark, in his treatise on the Steam-engine, also in his Pocket-book, gives the following formula:  $p = 407ts \div d$ , in which *p* is the internal pressure in pounds per square inch that will strain the plates to their elastic limit, *t* is the thickness of the plate in inches, *d* is the distance between two rows of stay-bolts in the clear, and *s* is the tensile stress in the plate in tons of 2240 lbs. per square inch, at the elastic limit. Substituting values of *s* for iron, steel, and copper, 12, 14, and 8 tons respectively, we have the following:

FORMULÆ FOR ULTIMATE ELASTIC STRENGTH OF FLAT STAYED SURFACES.

	Iron.	Steel.	Copper.
Pressure.....	$p = 5000 \frac{t}{d}$	$p = 5700 \frac{t}{d}$	$p = 3300 \frac{t}{d}$
Thickness of plate.....	$t = \frac{p \times d}{5000}$	$t = \frac{p \times d}{5700}$	$t = \frac{p \times d}{3300}$
Pitch of bolts.....	$d = \frac{5000t}{p}$	$d = \frac{5700t}{p}$	$d = \frac{3300t}{p}$

**For Diameter of the Stay-bolts,** Clark gives  $d' = .0024 \sqrt{\frac{PP'p}{s}}$ ,

in which  $d'$  = diameter of screwed bolt at bottom of thread,  $P$  = longitudinal and  $P'$  transverse pitch of stay-bolts between centres,  $p$  = internal pressure in lbs. per sq. in. that will strain the plate to its elastic limit,  $s$  = elastic strength of the stay-bolts in lbs. per sq. in. Taking  $s = 12, 14,$  and  $8$  tons, respectively for iron, steel, and copper, we have

For iron,  $d' = .00069 \sqrt{PP'p}$ , or if  $P = P'$ ,  $d' = .00069P \sqrt{p}$ ;

For steel,  $d' = .00064 \sqrt{PP'p}$ , " "  $d' = .00064P \sqrt{p}$ ;

For copper,  $d' = .00084 \sqrt{PP'p}$ , " "  $d' = .00084P \sqrt{p}$ .

In using these formulæ a large factor of safety should be taken to allow for reduction of size by corrosion. Thurston's Manual of Steam-boilers, p. 144, recommends that the factor be as large as 15 or 20. The Hartford Steam Boiler Insp. & Ins. Co. recommends not less than 10.

**Strength of Stays.**—A. F. Yarrow (*Engr.*, March 20, 1891) gives the following results of experiments to ascertain the strength of water-space stays :

Description.	Length between Plates.	Diameter of Stay over Threads.	Ultimate Stress.
			lbs.
Hollow stays screwed into plates and hole expanded }	4.75 in.	1 in. (hole $\frac{7}{16}$ in. and $\frac{5}{16}$ in.)	25,457
	4.64 in.	1 in. (hole $\frac{9}{16}$ in. and $\frac{7}{16}$ in.)	20,992
Solid stays screwed into plates and riveted over. }	4.80 in.	$\frac{7}{8}$ in.	22,008
	4.80 in.	$\frac{7}{8}$ in.	22,070

The above are taken as a fair average of numerous tests.

**Stay-bolts in Curved Surfaces, as in Water-legs of Vertical Boilers.**—The rules of the U. S. Supervising Inspectors provide as follows: All vertical boiler-furnaces constructed of wrought iron or steel plates, and having a diameter of over 42 in. or a height of over 40 in. shall be stayed with bolts as provided by § 6 of Rule II, for flat surfaces; and the thickness of material required for the shells of such furnaces shall be determined by the distance between the centres of the stay-bolts in the furnace and not in the shell of the boiler; and the steam-pressure allowable shall be determined by the distance from centre of stay-bolts in the furnace and the diameter of such stay-bolts at the bottom of the thread.

The Hartford Steam-boiler Insp. & Ins. Co. approves the above rule (*The Locomotive*, March, 1892) as far as it states that curved surfaces are to be computed the same as flat ones, but prefers Clark's formulæ for flat stayed surfaces to the rules of the U. S. Supervising Inspectors.

**Fusible-plugs.**—Fusible-plugs should be put in that portion of the heating-surface which first becomes exposed from lack of water. The rules of the U. S. Supervising Inspectors specify Banca tin for the purpose. Its melting-point is about 445° F. The rule says: All steamers shall have inserted in their boilers plugs of Banca tin, at least  $\frac{1}{2}$  in. in diameter at the smallest end of the internal opening, in the following manner, to wit: Cylinder-boilers with flues shall have one plug inserted in one flue of each boiler; and also one plug inserted in the shell of each boiler from the inside, immediately before the fire line and not less than 4 ft. from the forward end of the boiler. All fire-box boilers shall have one plug inserted in the crown of the back connection, or in the highest fire-surface of the boiler.

All upright tubular boilers used for marine purposes shall have a fusible plug inserted in one of the tubes at a point at least 2 in. below the lower gauge-cock, and said plug may be placed in the upper head sheet when deemed advisable by the local inspectors.

**Steam-domes.**—Steam domes or drums were formerly almost universally used on horizontal boilers, but their use is now generally discontinued, as they are considered a useless appendage to a steam-boiler, and unless properly designed and constructed are an element of weakness.

**Height of Furnace.**—Recent practice in the United States makes the height of furnace much greater than it was formerly. With large sizes of anthracite there is no serious objection to having the furnace as low as 12 to 18 in., measured from the surface of the grate to the nearest portion of the heating-surface of the boiler, but with coal containing much volatile matter and moisture a much greater distance is desirable. With very volatile coals the distance may be as great as 4 or 5 ft. Rankine (S. E., p. 457) says: The clear height of the "crown" or roof of the furnace above the grate-bars is seldom less than about 18 in., and often considerably more. In the fire-boxes of locomotives it is on an average about 4 ft. The height of 18 in. is suitable where the crown of the furnace is a brick arch. Where the crown of the furnace, on the other hand, forms part of the heating-surface of the boiler, a greater height is desirable in every case in which it can be obtained; for the temperature of the boiler-plates, being much lower than that of the flame, tends to check the combustion of the inflammable gases which rise from the fuel. As a general principle a high furnace is favorable to complete combustion.

## IMPROVED METHODS OF FEEDING COAL,

**Mechanical Stokers.** (William R. Roney, Trans. A. S. M. E., vol. xii.)—Mechanical stokers have been used in England to a limited extent since 1785. In that year one was patented by James Watt. It was a simple device to push the coal, after it was coked at the front end of the grate, back towards the bridge. It was worked intermittently by levers, and was designed primarily to prevent smoke from bituminous coal. (See D. K. Clark's Treatise on the Steam-engine.)

After the year 1840 many styles of mechanical stokers were patented in England, but nearly all were variations and modifications of the two forms of stokers patented by John Jukes in 1841, and by E. Henderson in 1843.

The Jukes stoker consisted of longitudinal fire-bars, connected by links, so as to form an endless chain, similar to the familiar treadmill horse-power. The small coal was delivered from a hopper on the front of the boiler, on to the grate, which slowly moving from front to rear, gradually advanced the fuel into the furnace and discharged the ash and clinker at the back.

The Henderson stoker consists primarily of two horizontal fans revolving on vertical spindles, which scatter the coal over the fire.

Numerous faults in mechanical construction and in operation have limited the use of these and other mechanical stokers. The first American stoker was the Murphy stoker, brought out in 1878. It consists of two coal magazines placed in the side walls of the boiler furnace, and extending back from the boiler front 6 or 7 feet. In the bottom of these magazines are rectangular iron boxes, which are moved from side to side by means of a rack and pinion, and serve to push the coal upon the grates, which incline at an angle of about 35° from the inner edge of the coal magazines, forming a V-shaped receptacle for the burning coal. The grates are composed of narrow parallel bars, so arranged that each alternate bar lifts about an inch at the lower end, while at the bottom of the V, and filling the space between the ends of the grate-bars, is placed a cast-iron toothed bar, arranged to be turned by a crank. The purpose of this bar is to grind the clinker coming in contact with it. Over this V-shaped receptacle is sprung a fire-brick arch.

In the Roney mechanical stoker the fuel to be burned is dumped into a hopper on the boiler front. Set in the lower part of the hopper is a "pusher" to which is attached the "feed-plate" forming the bottom of the hopper. The "pusher," by a vibratory motion, carrying with it the "feed-plate," gradually forces the fuel over the "dead-plate" and on the grate. The grate-bars, in their normal condition form a series of steps, to the top step of which coal is fed from the "dead-plate." Each bar rests in a concave seat in the bearer, and is capable of a rocking motion through an adjustable angle. All the grate-bars are coupled together by a "rocker-bar." A variable back-and-forth motion being given to the "rocker-bar," through a con-

necting-rod, the grate-bars rock in unison, now forming a series of steps, and now approximating to an inclined plane, with the grates partly overlapping, like shingles on a roof. When the grate-bars rock forward the fire will tend to work down in a body. But before the coal can move too far the bars rock back to the stepped position, checking the downward motion, breaking up the cake over the whole surface, and admitting a free volume of air through the fire. The rocking motion is slow, being from 7 to 10 strokes per minute, according to the kind of coal. This alternate starting and checking motion is continuous, and finally lands the cinder and ash on the dumping-grate below.

Mr. Roney gives the following record of six tests to determine the comparative economy of the Roney mechanical stoker and hand-firing on return tubular boilers, 60 inches  $\times$  20 feet, burning Cumberland coal with natural draught. Rating of boiler at 12.5 square feet, 105 H. P.

	Three tests, hand-firing.			Three tests, Stoker.		
Evaporation per pound, dry	10.36	10.44	11.00	11.89	12.25	12.54
coal from and at 212° lbs						
H.P. developed above rating, %	5.8	13.5	68	54.6	66.7	84.3

Results of comparative tests like the above should be used with caution in drawing generalizations. It by no means follows from these results that a stoker will always show such comparative excellence, for in this case the results of hand-firing are much below what may be obtained under favorable circumstances from hand-firing with good Cumberland coal.

**The Hawley Down-draught Furnace.**—A foot or more above the ordinary grate there is carried a second grate composed of a series of water tubes, opening at both ends into steel drums or headers, through which water is circulated. The coal is fed on this upper grate, and as it is partially consumed falls through it upon the lower grate, where the combustion is completed in the ordinary manner. The draught through the coal on the upper grate is downward through the coal and the grate. The volatile gases are therefore carried down through the bed of coal, where they are thoroughly heated, and are burned in the space beneath, where they meet the excess of hot air drawn through the fire on the lower grate. In tests in Chicago, from 30 to 45 lbs. of coal were burned per square foot of grate upon this system, with good economical results. (See catalogue of the Hawley Down Draught Furnace Co., Chicago.)

**Under-feed Stokers.**—Results similar to those that may be obtained with downward draught are obtained by feeding the coal at the bottom of the bed, pushing upward the coal already on the bed which has had its volatile matter distilled from it. The volatile matter of the freshly fired coal then has to pass through a body of ignited coke, where it meets a supply of hot air. (See circular of The American Stoker Co., New York, 1898.)

### SMOKE PREVENTION.

A committee of experts was appointed in St. Louis in 1891 to report on the smoke problem. A summary of its report is given in the *Iron Age* of April 7, 1892. It describes the different means that have been tried to prevent smoke, such as gas-fuel, steam-jets, fire-brick arches and checker-work, hollow walls for preheating air, coking arches or chambers, double combustion furnaces, and automatic stokers. All of these means have been more or less effective in diminishing smoke, their effectiveness depending largely upon the skill with which they are operated; but none is entirely satisfactory. Fuel-gas is objectionable chiefly on account of its expense. The average quality of fuel-gas made from a trial run of several car-loads of Illinois coal, in a well-designed fuel-gas plant, showed a calorific value of 243,391 heat-units per 1000 cubic feet. This is equivalent to 5052.8 heat-units per lb. of coal, whereas by direct calorimeter test an average sample of the coal gave 11,172 heat-units. One lb. of the coal showed a theoretical evaporation of 11.56 lbs. water, while the gas from 1 lb. showed a theoretical evaporation of 5.23 lbs. 48.17 lbs. of coal were required to furnish 1000 cubic feet of the gas. In 39 tests the smoke-preventing furnaces showed only 74% of the capacity of the common furnaces, reduced the work of the boilers 28%, and required about 2% more fuel to do the same work. In one case with steam-jets the fuel consumption was increased 12% for the same work.

Prof. O. H. Landreth, in a report to the State Board of Health of Tennessee (*Engineering News*, June 8, 1893), writes as follows on the subject of smoke prevention:

As pertains to steam-boilers, the object must be attained by one or more of the following agencies :

1. Proper design and setting of the boiler-plant. This implies proper grate area, sufficient draught, the necessary air-space between grate-bars and through furnace, and ample combustion-room under boilers.

2. That system of firing that is best adapted to each particular furnace to secure the perfect combustion of bituminous coal. This may be either: (a) "coke-firing," or charging all coal into the front of the furnace until partially coked, then pushing back and spreading; or (b) "alternate side-firing"; or (c) "spreading," by which the coal is spread over the whole grate area in thin, uniform layers at each charging.

3. The admission of air through the furnace-door, bridge-wall, or side walls.

4. Steam-jets and other artificial means for thoroughly mixing the air and combustible gases.

5. Preventing the cooling of the furnace and boilers by the inrush of cold air when the furnace-doors are opened for charging coal and handling the fire.

6. Establishing a gradation of the several steps of combustion so that the coal may be charged, dried, and warmed at the coolest part of the furnace, and then moved by successive steps to the hottest place, where the final combustion of the coked coal is completed, and compelling the distilled combustible gases to pass through this hottest part of the fire.

7. Preventing the cooling by radiation of the unburned combustible gases until perfect mixing and combustion have been accomplished.

8. Varying the supply of air to suit the periodic variation in demand.

9. The substitution of a continuous uniform feeding of coal instead of intermittent charging.

10. Down-draught burning or causing the air to enter above the grate and pass down through the coal, carrying the distilled products down to the high temperature plane at the bottom of the fire.

The number of smoke-prevention devices which have been invented is legion. A brief classification is :

(a) Mechanical stokers. They effect a material saving in the labor of firing, and are efficient smoke-preventers when not pushed above their capacity, and when the coal does not cake badly. They are rarely susceptible to the sudden changes in the rate of firing frequently demanded in service.

(b) Air-flues in side walls, bridge-wall, and grate-bars, through which air when passing is heated. The results are always beneficial, but the flues are difficult to keep clean and in order.

(c) Coking arches, or spaces in front of the furnace arched over, in which the fresh coal is coked, both to prevent cooling of the distilled gases, and to force them to pass through the hottest part of the furnace just beyond the arch. The results are good for normal conditions, but ineffective when the fires are forced. The arches also are easily burned out and injured by working the fire.

(d) Dead-plates, or a portion of the grate next the furnace-doors, reserved for warming and coking the coal before it is spread over the grate. These give good results when the furnace is not forced above its normal capacity. This embodies the method of "coke-firing" mentioned before.

(e) Down-draught furnaces, or furnaces in which the air is supplied to the coal above the grate, and the products of combustion are taken away from beneath the grate, thus causing a downward draught through the coal, carrying the distilled gases down to the highly heated incandescent coal at the bottom of the layer of coal on the grate. This is the most perfect manner of producing combustion, and is absolutely smokeless.

(f) Steam-jets to draw air in or inject air into the furnace above the grate, and also to mix the air and the combustible gases together. A very efficient smoke-preventer, but one liable to be wasteful of fuel by inducing too rapid a draught.

(g) Baffle-plates placed in the furnace above the fire to aid in mixing the combustible gases with the air.

(h) Double furnaces, of which there are two different styles; the first of which places the second grate below the first grate; the coal is coked on the first grate, during which process the distilled gases are made to pass over the second grate, where they are ignited and burned; the coke from the first grate is dropped onto the second grate: a very efficient and economical smoke-preventer, but rather complicated to construct and maintain. In the second form the products of combustion from the first furnace pass through

the grate and fire of the second, each furnace being charged with fresh fuel when needed, the latter generally with a smokeless coal or coke: an irrational and unpromising method.

Mr. C. F. White, Consulting Engineer to the Chicago Society for the Prevention of Smoke, writes under date of May 4, 1893:

The experience had in Chicago has shown plainly that it is perfectly easy to equip steam-boilers with furnaces which shall burn ordinary soft coal in such a manner that the making of smoke dense enough to obstruct the vision shall be confined to one or two intervals of perhaps a couple of minutes' duration in the ordinary day of 10 hours.

**Gas-fired Steam-boilers.**—Converting coal into gas in a separate producer, before burning it under the steam-boiler, is an ideal method of smoke-prevention, but its expense has hitherto prevented its general introduction. A series of articles on the subject, illustrating a great number of devices, by F. J. Rowan, is published in the *Colliery Engineer*, 1889-90. See also Clark on the Steam-engine.

### FORCED COMBUSTION IN STEAM-BOILERS.

For the purpose of increasing the amount of steam that can be generated by a boiler of a given size, forced draught is of great importance. It is universally used in the locomotive, the draught being obtained by a steam-jet in the smoke-stack. It is now largely used in ocean steamers, especially in ships of war, and to a small extent in stationary boilers. Economy of fuel is generally not attained by its use, its advantages being confined to the securing of increased capacity from a boiler of a given bulk, weight, or cost. The subject of forced draught is well treated in a paper by James Howden, entitled, "Forced Combustion in Steam-boilers" (Section G, Engineering Congress at Chicago, in 1893), from which we abstract the following:

Edwin A. Stevens at Bordentown, N. J., in 1827, in the steamer "North America," fitted the boilers with closed ash-pits, into which the air of combustion was forced by a fan. In 1828 Ericsson fitted in a similar manner the steamer "Victory," commanded by Sir John Ross.

Messrs. E. A. and R. L. Stevens continued the use of forced draught for a considerable period, during which they tried three different modes of using the fan for promoting combustion: 1, blowing direct into a closed ash-pit; 2, exhausting the base of the funnel by the suction of the fan; 3, forcing air into an air-tight boiler-room or stoke-hold. Each of these three methods was attended with serious difficulties.

In the use of the closed ash-pit the blast-pressure would frequently force the gases of combustion, in the shape of a serrated flame, from the joint around the furnace doors in so great a quantity as to affect both the efficiency and health of the firemen.

The chief defect of the second plan was the great size of the fan required to produce the necessary exhaustion. The size of fan required grows in a rapidly increasing ratio as the combustion increases, both on account of the greater air-supply and the higher exit temperature enlarging the volume of the waste gases.

The third method, that of forcing cold air by the fan into an air-tight boiler-room—the present closed stoke-hold system—though it overcame the difficulties in working belonging to the two forms first tried, has serious defects of its own, as it cannot be worked, even with modern high-class boiler-construction, much, if at all, above the power of a good chimney draught, in most boilers, without damaging them.

In 1875 John I. Thornycroft & Co., of London, began the construction of torpedo-boats with boilers of the locomotive type, in which a high rate of combustion was attained by means of the air-tight boiler-room, into which air was forced by means of a fan.

In 1882 H. B. M. ships "Satellite" and "Conqueror" were fitted with this system, the former being a small ship of 1500 I.H.P., and the latter an iron-clad of 4500 I.H.P. On the trials with forced draught, which lasted from two to three hours each, the highest rates of combustion gave 16.9 I.H.P. per square foot of fire-grate in the "Satellite," and 13.41 I.H.P. in the "Conqueror."

None of the short trials at these rates of combustion were made without injury to the seams and tubes of the boilers, but the system was adopted, and it has been continued in the British Navy to this day (1893).

In Mr. Howden's opinion no advantage arising from increased combustion over natural-draught rates is derived from using forced draught in a closed ash-pit sufficient to compensate the disadvantages arising from difficulties

in working, there being either excessive smoke from bituminous coal or reduced evaporative economy.

In 1880 Mr. Howden designed an arrangement intended to overcome the defects of both the closed ash-pit and closed stoke-hold systems.

An air-tight reservoir or chamber is placed on the front end of the boiler and surrounding the furnaces. This reservoir, which projects from 8 to 10 inches from the end of the boiler, receives the air under pressure, which is passed by the valves into the ash-pits and over the fires in proportions suited to the kind of fuel used and the rate of combustion required. The air used above the fires is admitted to a space between the outer and inner furnace-doors, the inner having perforations and an air-distributing box through which the air passes under pressure.

By means of the balance of air-pressure above and below the fires all tendency for the fire to blow out at the furnace-door is removed.

By regulating the admission of the air by the valves above and below the fires, the highest rate of combustion possible by the air-pressure used can be effected, and in same manner the rate of combustion can be reduced to far below that of natural draught, while complete and economical combustion at all rates is secured.

A feature of the system is the combination of the heating of the air of combustion by the waste gases with the controlled and regulated admission of air to the furnaces. This arrangement is effected most conveniently by passing the hot fire-gases after they leave the boiler through stacks of vertical tubes enclosed in the uptake, their lower ends being immediately above the smoke-box doors.

Installations on Howden's system have hitherto been arranged for a rate of combustion to give at full sea-power an average of from 18 to 22 I.H.P. per square foot of fire-grate with fire-bars from 5' 0'' to 5' 6'' in length.

It is believed that with suitable arrangement of proportions even 30 I.H.P. per square foot can be obtained.

For an account of recent uses of exhaust-fans for increasing draught, see paper by W. R. Roney, Trans. A. S. M. E., vol. xv.

**FUEL ECONOMIZERS.**

**Green's Fuel Economizer.**—Clark gives the following average results of comparative trials of three boilers at Wigan used with and without economizers :

	Without Economizers.	With Economizers.
Coal per square foot of grate per hour.....	21.6	21.4
Water at 100° evaporated per hour.....	73.55	79.32
Water at 212° per pound of coal....	9.60	10.56

Showing that in burning equal quantities of coal per hour the rapidity of evaporation is increased 9.3% and the efficiency of evaporation 10% by the addition of the economizer.

The average temperatures of the gases and of the feed-water before and after passing the economizer were as follows:

	With 6-ft. grate.		With 4-ft. grate.	
	Before.	After.	Before.	After.
Average temperature of gases.....	649	340	501	312
Average temperature of feed-water.	47	157	41	137

Taking averages of the two grates, to raise the temperature of the feed-water 100° the gases were cooled down 250°.

**Performance of a Green Economizer with a Smoky Coal.**—The action of Green's Economizer was tested by M. W. Grosseteste for a period of three weeks. The apparatus consists of four ranges of vertical pipes, 6½ feet high, 3¾ inches in diameter outside, nine pipes in each range, connected at top and bottom by horizontal pipes. The water enters all the tubes from below, and leaves them from above. The system of pipes is enveloped in a brick casing, into which the gaseous products of combustion are introduced from above, and which they leave from below. The pipes are cleared of soot externally by automatic scrapers. The capacity for water is 24 cubic feet, and the total external heating-surface is 290 square feet. The apparatus is placed in connection with a boiler having 355 square feet of surface.

This apparatus had been at work for seven weeks continuously without having been cleaned, and had accumulated a ½-inch coating of soot and

ash, when its performance, in the same condition, was observed for one week. During the second week it was cleaned twice every day; but during the third week, after having been cleaned on Monday morning, it was worked continuously without further cleaning. A smoke-making coal was used. The consumption was maintained sensibly constant from day to day.

GREEN'S ECONOMIZER.—RESULTS OF EXPERIMENTS ON ITS EFFICIENCY AS AFFECTED BY THE STATE OF THE SURFACE. (W. Grosseteste.)

TIME (February and March).	Temperature of Feed-water.			Temperature of Gaseous Products.		
	Enter- ing Feed- heater.	Leav- ing Feed- heater.	Differ- ence.	Enter- ing Feed- heater.	Leav- ing Feed- heater.	Differ- ence.
	Fahr.	Fahr.	Fahr.	Fahr.	Fahr.	Fahr.
1st Week .....	73.5°	161.5°	88.0°	849°	261°	588°
2d Week.....	77.0	230 0	153.0	882	297	585
3d Week—Monday .....	73.4	196.0	122.6	831	284	547
Tuesday .....	73.4	181 4	108.0	871	309	562
Wednesday.....	79.0	178.0	99.0	—	—	—
Thursday.....	80.6	170.6	90.0	952	329	623
Friday.....	80.6	169 0	88.4	889	338	551
Saturday.....	79.0	172.4	93.4	901	351	550

	1st Week.	2d Week.	3d Week.
Coal consumed per hour.....	214 lbs.	216 lbs.	213 lbs.
Water evaporated from 32° F. per hour..	1424	1525	1428
Water per pound of coal....	6.65	7.06	6.70

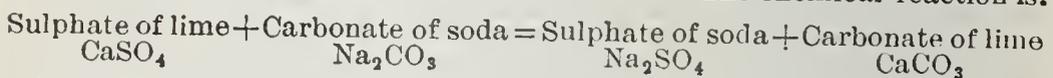

It is apparent that there is a great advantage in cleaning the pipes daily—the elevation of temperature having been increased by it from 88° to 153°. In the third week, without cleaning, the elevation of temperature relapsed in three days to the level of the first week; even on the first day it was quickly reduced by as much as half the extent of relapse. By cleaning the pipes daily an increased elevation of temperature of 65° F., was obtained, whilst a gain of 6% was effected in the evaporative efficiency.

## INCRUSTATION AND CORROSION.

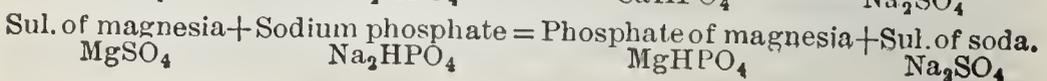

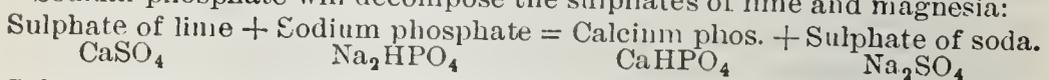

**Incrustation and Scale.**—Incrustation (as distinguished from mere sediments due to dirty water, which are easily blown out, or gathered up, by means of sediment-collectors) is due to the presence of salts in the feed-water (carbonates and sulphates of lime and magnesia for the most part), which are precipitated when the water is heated, and form hard deposits upon the boiler-plates. (See Impurities in Water, p. 551, *ante*.)

Where the quantity of these salts is not very large (12 grains per gallon, say) scale preventives may be found effective. The chemical preventives either form with the salts other salts soluble in hot water; or precipitate them in the form of soft mud, which does not adhere to the plates, and can be washed out from time to time. The selection of the chemical must depend upon the composition of the water, and it should be introduced regularly with the feed.

**EXAMPLES.**—Sulphate-of-lime scale prevented by carbonate of soda: The sulphate of soda produced is soluble in water; and the carbonate of lime falls down in grains, does not adhere to the plates, and may therefore be blown out or gathered into sediment-collectors. The chemical reaction is:

Sodium phosphate will decompose the sulphates of lime and magnesia:

Where the quantity of salts is large, scale preventives are not of much use. Some other source of supply must be sought, or the bad water purified before it is allowed to enter the boilers. The damage done to boilers by unsuitable water is enormous.

Pure water may be obtained by collecting rain, or condensing steam by means of surface condensers. The water thus obtained should be mixed with a little bad water, or treated with a little alkali, as undiluted, pure water corrodes iron; or, after each periodic cleaning, the bad may be used for a day or two to put a skin upon the plates.

Carbonate of lime and magnesia may be precipitated either by heating the water or by mixing milk of lime (Porter Clark process) with it, the water being then filtered.

Corrosion may be produced by the use of pure water, or by the presence of acids in the water, caused perhaps in the engine-cylinder by the action of high-pressure steam upon the grease, resulting in the production of fatty acids. Acid water may be neutralized by the addition of lime.

**Amount of Sediment** which may collect in a 100-H.P. steam-boiler, evaporating 3000 lbs. of water per hour, the water containing different amounts of impurity in solution, provided that no water is blown off:

Grains of solid impurities per U. S. gallon:										
5	10	20	30	40	50	60	70	80	90	100
Equivalent parts per 100,000:										
8.57	17.14	34.28	51.42	68.56	85.71	102.85	120	137.1	154.3	171.4
Sediment deposited in 1 hour, pounds:

In one week of 6 days, pounds:										
15.43	30.85	61.7	92.55	123.4	154.3	185.1	216.0	246.8	277.6	308.5

If a 100-H.P. boiler has 1200 sq. ft. heating-surface, one week's running without blowing off, with water containing 100 grains of solid matter per gallon in solution, would make a scale nearly .02 in. thick, if evenly deposited all over the heating-surface, assuming the scale to have a sp. gr. of 2.5 = 156 lbs. per cu. ft.;  $.02 \times 1200 \times 156 \times 1/12 = 312$  lbs.

**Boiler-scale Compounds.**—The Bavarian Steam-boiler Inspection Assn. in 1885 reported as follows:

Generally the unusual substances in water can be retained in soluble form or precipitated as mud by adding caustic soda or lime. This is especially desirable when the boilers have small interior spaces.

It is necessary to have a chemical analysis of the water in order to fully determine the kind and quantity of the preparation to be used for the above purpose.

All secret compounds for removing boiler-scale should be avoided. (A list of 27 such compounds manufactured and sold by German firms is then given which have been analyzed by the association.)

Such secret preparations are either nonsensical or fraudulent, or contain either one of the two substances recommended by the association for removing scale, generally soda, which is colored to conceal its presence, and sometimes adulterated with useless or even injurious matter.

These additions as well as giving the compound some strange, fanciful name, are meant simply to deceive the boiler owner and conceal from him the fact that he is buying colored soda or similar substances, for which he is paying an exorbitant price.

The Chicago, Milwaukee & St. P. R. R. uses for the prevention of scale in locomotive-boilers an alkaline compound consisting of 3750 gals. of water, 2600 lbs. of 70% caustic soda, and 1600 lbs. of 58% soda-ash (*Eng. News*, Dec. 5, 1891).

Mr. H. E. Smith, chemist of the Ry. Co., writes May, 1902, that this compound was abandoned several years ago and commercial soda-ash, known as "58° soda," containing about 97% pure carbonate of soda, substituted in the water in the locomotive tender tanks, where it dissolves and passes to the boiler. Its action is to precipitate a portion of the scale forming solids in a flocculent form so that they are kept loose and free from the metal until they can be blown or washed out.

The amounts used vary according to the character of the water and are based on the following rules: For calcium and magnesium sulphates and

chlorides, use soda-ash equal to the chemical equivalent of those compounds present. For calcium and magnesium carbonates, the amount of soda-ash to be used varies from nothing when sulphates or chlorides are high, up to about one fifth the equivalent of the carbonates, when sulphates and chlorides are low or absent. A few waters contain carbonate of soda originally, and for these less soda-ash or none at all is necessary. It may also be necessary to make some reduction in the dose of soda-ash when large amounts of other alkali salts are present. In any case it is not desirable to use more than 2 lbs. of soda-ash per 1000 gallons of water, or more than 10 lbs. per 100 miles of locomotive run, on account of the foaming produced. The above rule assumes that the boilers are fairly clean and are kept fairly free from sludge by blowing and washing out. On the C., M. & St. P. Ry. boilers are usually washed once in 500 to 2000 miles run, according to the character of the waters used.

In the upper Mississippi valley the majority of the waters are below 20 or 25 grains of incrusting solids per gallon, and the greater portion of this is carbonates. For these the above treatment is very successful. From 25 to 50 grains, increasing difficulty is encountered on account of foaming produced by the large amounts of sludge and alkali, and above 50 grains, soda-ash alone fails to keep the boilers clean in practical service.

**Kerosene and other Petroleum Oils; Foaming.**—Kerosene has recently been highly recommended as a scale preventive. See paper by L. F. Lyne (Trans. A. S. M. E., ix, 247). The *Am. Mach.*, May 22, 1890, says: Kerosene used in moderate quantities will not make the boiler foam; it is recommended and used for loosening the scale and for preventing the formation of scale. The presence of oil in combination with other impurities increases the tendency of many boilers to foam, as the oil with the impurities impedes the free escape of steam from the water surface. The use of common oil not only tends to cause foaming, but is dangerous otherwise. The grease appears to combine with the impurities of the water, and when the boiler is at rest this compound sinks to the plates and clings to them in a loose, spongy mass, preventing the water from coming in contact with the plates, and thereby producing overheating, which may lead to an explosion. Foaming may also be caused by forcing the fire, or by taking the steam from a point over the furnace or where the ebullition is violent; the greasy and dirty state of new boilers is another good cause for foaming. Kerosene should be used at first in small quantities, the effect carefully noted, and the quantity increased if necessary for obtaining the desired results.

R. C. Carpenter (Trans. A. S. M. E., vol. xi.) says: The boilers of the State Agricultural College at Lansing, Mich., were badly incrustated with a hard scale. It was fully three eighths of an inch thick in many places. The first application of the oil was made while the boilers were being but little used, by inserting a gallon of oil, filling with water, heating to the boiling-point and allowing the water to stand in the boiler two or three weeks before removal. By this method fully one half the scale was removed during the warm season and before the boilers were needed for heavy firing. The oil was then added in small quantities when the boiler was in actual use. For boilers 4 ft. in diam. and 12 ft. long the best results were obtained by the use of 2 qts. for each boiler per week, and for each boiler 5 ft. in diam. 3 qts. per week. The water used in the boilers has the following analysis:  $\text{CaCO}_3$ , 206 parts in a million;  $\text{MgCO}_3$ , 78 parts;  $\text{Fe}_2\text{CO}_3$ , 22 parts; traces of sulphates and chlorides of potash and soda. Total solids, 325 parts in 1,000,000.

**Tannate of Soda Compound.**—T. T. Parker writes to *Am. Mach.*: Should you find kerosene not doing any good, try this recipe: 50 lbs. sal-soda, 35 lbs. japonica; put the ingredients in a 50-gal. barrel, fill half full of water, and run a steam hose into it until it dissolves and boils. Remove the hose, fill up with water, and allow to settle. Use one quart per day of ten hours for a 40-H.P. boiler, and, if possible, introduce it as you do cylinder-oil to your engine. Barr recommends tannate of soda as a remedy for scale composed of sulphate and carbonate of lime. As the japonica yields the tannic acid, I think the resultant equivalent to the tannate of soda.

**Petroleum Oils** heavier than kerosene have been used with good results. Crude oil should never be used. The more volatile oils it contains make explosive gases, and its tarry constituents are apt to form a spongy incrustation.

**Removal of Hard Scale.**—When boilers are coated with a hard scale difficult to remove the addition of  $\frac{1}{4}$  lb. caustic soda per horse-power, and steaming for some hours, according to the thickness of the scale, just before cleaning, will greatly facilitate that operation, rendering the scale

soft and loose. This should be done, if possible, when the boilers are not otherwise in use. (*Steam.*)

**Corrosion in Marine Boilers.** (Proc. Inst. M. E., Aug. 1884).—The investigations of the Committee on Boilers served to show that the internal corrosion of boilers is greatly due to the combined action of air and sea-water when under steam, and when not under steam to the combined action of air and moisture upon the unprotected surfaces of the metal. There are other deleterious influences at work, such as the corrosive action of fatty acids, the galvanic action of copper and brass, and the inequalities of temperature; these latter, however, are considered to be of minor importance.

Of the several methods recommended for protecting the internal surfaces of boilers, the three found most effectual are: First, the formation of a thin layer of hard scale, deposited by working the boiler with sea-water; second, the coating of the surfaces with a thin wash of Portland cement, particularly wherever there are signs of decay; third, the use of zinc slabs suspended in the water and steam spaces.

As to general treatment for the preservation of boilers in store or when laid up in the reserve, either of the two following methods is adopted, as may be found most suitable in particular cases. First, the boilers are dried as much as possible by airing-stoves, after which 2 to 3 cwt. of quick-lime, according to the size of the boiler, is placed on suitable trays at the bottom of the boiler and on the tubes. The boiler is then closed and made as air-tight as possible. Periodical inspection is made every six months, when if the lime be found slacked it is renewed. Second, the other method is to fill the boilers up with sea or fresh water, having added soda to it in the proportion of 1 lb. of soda to every 100 or 120 lbs. of water. The sufficiency of the saturation can be tested by introducing a piece of clean new iron and leaving it in the boiler for ten or twelve hours; if it shows signs of rusting, more soda should be added. It is essential that the boilers be entirely filled, to the complete exclusion of air.

Great care is taken to prevent sudden changes of temperature in boilers. Directions are given that steam shall not be raised rapidly, and that care shall be taken to prevent a rush of cold air through the tubes by too suddenly opening the smoke-box doors. The practice of emptying boilers by blowing out is also prohibited, except in cases of extreme urgency. As a rule the water is allowed to remain until it becomes cool before the boilers are emptied.

Mineral oil has for many years been exclusively used for internal lubrication of engines, with the view of avoiding the effects of fatty acid, as this oil does not readily decompose and possesses no acid properties.

Of all the preservative methods adopted in the British service, the use of zinc properly distributed and fixed has been found the most effectual in saving the iron and steel surfaces from corrosion, and also in neutralizing by its own deterioration the hurtful influences met with in water as ordinarily supplied to boilers. The zinc slabs now used in the navy boilers are 12 in. long, 6 in. wide, and  $\frac{1}{2}$  inch thick; this size being found convenient for general application. The amount of zinc used in new boilers at present is one slab of the above size for every 20 I.H.P., or about one square foot of zinc surface to two square feet of grate surface. Rolled zinc is found the most suitable for the purpose. To make the zinc properly efficient as a protector especial care must be taken to insure perfect metallic contact between the slabs and the stays or plates to which they are attached. The slabs should be placed in such positions that all the surfaces in the boiler shall be protected. Each slab should be periodically examined to see that its connection remains perfect, and to renew any that may have decayed; this examination is usually made at intervals not exceeding three months. Under ordinary circumstances of working these zinc slabs may be expected to last in fit condition from sixty to ninety days, immersed in hot sea-water; but in new boilers they at first decay more rapidly. The slabs are generally secured by means of iron straps 2 in. wide and  $\frac{3}{8}$  inch thick, and long enough to reach the nearest stay, to which the strap is firmly attached by screw-bolts.

To promote the proper care of boilers when not in use the following order has been issued to the French Navy by the Government: On board all ships in the reserve, as well as those which are laid up, the boilers will be completely filled with fresh water. In the case of large boilers with large tubes there will be added to the water a certain amount of milk of lime, or a solution of soda may be used instead. In the case of tubulous boilers with small tubes milk of lime or soda may be added, but the solution will not be

so strong as in the case of the larger tube, so as to avoid any danger of contracting the effective area by deposit from the solution; but the strength of the solution will be just sufficient to neutralize any acidity of the water. (*Iron Age*, Nov. 2, 1893.)

**Use of Zinc.**—Zinc is often used in boilers to prevent the corrosive action of water on the metal. The action appears to be an electrical one, the iron being one pole of the battery and the zinc being the other. The hydrogen goes to the iron shell and escapes as a gas into the steam. The oxygen goes to the zinc.

On account of this action it is generally believed that zinc will always prevent corrosion, and that it cannot be harmful to the boiler or tank. Some experiences go to disprove this belief, and in numerous cases zinc has not only been of no use, but has even been harmful. In one case a tubular boiler had been troubled with a deposit of scale consisting chiefly of organic matter and lime, and zinc was tried as a preventive. The beneficial action of the zinc was so obvious that its continued use was advised, with frequent opening of the boiler and cleaning out of detached scale until all the old scale should be removed and the boiler become clean. Eight or ten months later the water-supply was changed, it being now obtained from another stream supposed to be free from lime and to contain only organic matter. Two or three months after its introduction the tubes and shell were found to be coated with an obstinate adhesive scale, and composed of zinc oxide and the organic matter or sediment of the water used. The deposit had become so heavy in places as to cause overheating and bulging of the plates over the fire. (*The Locomotive*.)

**Effect of Deposit on Flues.** (Rankine.)—An external crust of a carbonaceous kind is often deposited from the flame and smoke of the furnaces in the flues and tubes, and if allowed to accumulate seriously impairs the economy of fuel. It is removed from time to time by means of scrapers and wire brushes. The accumulation of this crust is the probable cause of the fact that in some steamships the consumption of coal per indicated horse-power per hour goes on gradually increasing until it reaches one and a half times its original amount, and sometimes more.

**Dangerous Steam-boilers discovered by Inspection.**—The Hartford Steam-boiler Inspection and Insurance Co. reports that its inspectors during 1893 examined 163,328 boilers, inspected 66,698 boilers, both internally and externally, subjected 7861 to hydrostatic pressure, and found 597 unsafe for further use. The whole number of defects reported was 122,893, of which 12,390 were considered dangerous. A summary is given below. (*The Locomotive*, Feb. 1894.)

SUMMARY, BY DEFECTS, FOR THE YEAR 1893.

Nature of Defects.	Whole No.	Dan-gerous.	Nature of Defects.	Whole No.	Dan-gerous.
Deposit of sediment.....	9,774	548	Leakage around tubes..	21,211	2,909
Incrustation and scale...18,369		865	Leakage at seams... . .	5,424	482
Internal grooving..... .	1,249	148	Water-gauges defective.	3,670	660
Internal corrosion.....	6,252	397	Blow-outs defective.....	1,620	425
External corrosion.....	8,600	536	Deficiency of water.....	204	107
Def'tive braces and stays	1,966	485	Safety-valves overloaded	723	203
Settings defective.....	3,094	352	Safety-valves defective..	942	300
Furnaces out of shape... 4,575		254	Pressure-gauges def'tive	5,953	552
Fractured plates.....	3,532	640	Boilers without pressure-		
Burned plates.....	2,762	325	gauges. . . . .	115	115
Blistered plates.....	3,331	164	Unclassified defects....	755	4
Defective rivets.....	17,415	1,569			
Defective heads. ....	1,357	350	Total.....	122,893	12,390

The above-named company publishes annually a classified list of boiler-explosions, compiled chiefly from newspaper reports, showing that from 200 to 300 explosions take place in the United States every year, killing from 200 to 300 persons, and injuring from 300 to 450. The lists are not pretended to be complete, and may include only a fraction of the actual number of explosions.

**Steam-boilers as Magazines of Explosive Energy.**—Prof. R. H. Thurston (*Trans. A. S. M. E.*, vol. vi.), in a paper with the above title, presents calculations showing the stored energy in the hot water and steam of various boilers. Concerning the plain tubular boiler of the form and dimensions adopted as a standard by the Hartford Steam-boiler

Insurance Co., he says: It is 60 inches in diameter, containing 66 3-inch tubes, and is 15 feet long. It has 850 feet of heating and 30 feet of grate surface; is rated at 60 horse-power, but is oftener driven up to 75; weighs 9500 pounds, and contains nearly its own weight of water, but only 21 pounds of steam when under a pressure of 75 pounds per square inch, which is below its safe allowance. It stores 52,000,000 foot-pounds of energy, of which but 4 per cent is in the steam, and this is enough to drive the boiler just about one mile into the air, with an initial velocity of nearly 600 feet per second.

### SAFETY-VALVES.

#### Calculation of Weight, etc., for Lever Safety-valves.

Let  $W$  = weight of ball at end of lever, in pounds;

$w$  = weight of lever itself, in pounds;

$V$  = weight of valve and spindle, in pounds;

$L$  = distance between fulcrum and centre of ball, in inches;

$l$  = " " " " " " " valve, in inches;

$g$  = " " " " " " " gravity of lever, in in.;

$A$  = area of valve, in square inches;

$P$  = pressure of steam, in lbs. per sq. in., at which valve will open.

$$\text{Then } PA \times l = W \times L + w \times g + V \times l;$$

$$\text{whence } P = \frac{WL + wg + Vl}{Al};$$

$$W = \frac{PA l - wg - Vl}{L};$$

$$L = \frac{PA l - wg - Vl}{W}.$$

**EXAMPLE.**—Diameter of valve, 4"; distance from fulcrum to centre of ball, 36"; to centre of valve, 4"; to centre of gravity of lever,  $15\frac{1}{2}$ "; weight of valve and spindle, 3 lbs.; weight of lever, 7 lbs.; required the weight of ball to make the blowing-off pressure 80 lbs. per sq. in.; area of 4" valve = 12.566 sq. in. Then

$$W = \frac{PA l - wg - Vl}{L} = \frac{80 \times 12.566 \times 4 - 7 \times 15\frac{1}{2} - 3 \times 4}{36} = 108.4 \text{ lbs.}$$

The following rules governing the proportions of lever-valves are given by the U. S. Supervisors. The distance from the fulcrum to the valve-stem must in no case be less than the diameter of the valve-opening; the length of the lever must not be more than ten times the distance from the fulcrum to the valve-stem; the width of the bearings of the fulcrum must not be less than three quarters of an inch; the length of the fulcrum-link must not be less than four inches; the lever and fulcrum-link must be made of wrought iron or steel, and the knife-edged fulcrum points and the bearings for these points must be made of steel and hardened; the valve must be guided by its spindle, both above and below the ground seat and above the lever, through supports either made of composition (gun-metal) or bushed with it; and the spindle must fit loosely in the bearings or supports.

#### Rules for Area of Safety-valves.

(Rule of U. S. Supervising Inspectors of Steam-vessels (as amended 1894).)

Lever safety-valves to be attached to marine boilers shall have an area of not less than 1 sq. in. to 2 sq. ft. of the grate surface in the boiler, and the seats of all such safety-valves shall have an angle of inclination of  $45^\circ$  to the centre line of their axes.

Spring-loaded safety-valves shall be required to have an area of not less than 1 sq. in. to 3 sq. ft. of grate surface of the boiler, except as hereinafter otherwise provided for water-tube or coil and sectional boilers, and each spring-loaded valve shall be supplied with a lever that will raise the valve from its seat a distance of not less than that equal to one eighth the diameter of the valve-opening, and the seats of all such safety-valves shall have an angle of inclination to the centre line of their axes of  $45^\circ$ . All spring-loaded safety-valves for water-tube or coil and sectional boilers required to

carry a steam-pressure exceeding 175 lbs. per square inch shall be required to have an area of not less than 1 sq. in. to 6 sq. ft. of the grate surface of the boiler. Nothing herein shall be construed so as to prohibit the use of two safety-valves on one water-tube or coil and sectional boiler, provided the combined area of such valves is equal to that required by rule for one such valve.

**Rule in Philadelphia Ordinances: Bureau of Steam-engine and Boiler Inspection.**—Every boiler when fired separately, and every set or series of boilers when placed over one fire, shall have attached thereto, without the interposition of any other valve, two or more safety-valves, the aggregate area of which shall have such relations to the area of the grate and the pressure within the boiler as is expressed in schedule A.

**SCHEDULE A.**—Least aggregate area of safety-valve (being the least sectional area for the discharge of steam) to be placed upon all stationary boilers with natural or chimney draught [see note a].

$$A = \frac{22.5G}{P + 8.62},$$

in which  $A$  is area of combined safety-valves in inches;  $G$  is area of grate in square feet;  $P$  is pressure of steam in pounds per square inch to be carried in the boiler above the atmosphere.

The following table gives the results of the formula for one square foot of grate, as applied to boilers used at different pressures:

Pressures per square inch:

10    20    30    40    50    60    70    80    90    100    110    120

Area corresponding to one square foot of grate:

1.21   0.79   0.58   0.46   0.38   0.33   0.29   0.25   0.23   0.21   0.19   0.17

[Note a.] Where boilers have a forced or artificial draught, the inspector must estimate the area of grate at the rate of one square foot of grate-surface for each 16 lbs. of fuel burned on the average per hour.

**Comparison of Various Rules for Area of Lever Safety-valves.** (From an article by the author in *American Machinist*, May 24, 1894, with some alterations and additions.)—Assume the case of a boiler rated at 100 horse-power; 40 sq. ft. grate; 1200 sq. ft. heating-surface; using 400 lbs. of coal per hour, or 10 lbs. per sq. ft. of grate per hour, and evaporating 3600 lbs. of water, or 3 lbs. per sq. ft. of heating-surface per hour; steam-pressure by gauge, 100 lbs. What size of safety-valve, of the lever type, should be required?

A compilation of various rules for finding the area of the safety-valve disk, from *The Locomotive* of July, 1892, is given in abridged form below, together with the area calculated by each rule for the above example.

	Disk Area in sq. in.
U. S. Supervisors, heating-surface in sq. ft. $\div$ 25*	48
English Board of Trade, grate-surface in sq. ft. $\div$ 2	20
Molesworth, four fifths of grate-surface in sq. ft.	32
Thurston, 4 times coal burned per hour $\times$ (gauge pressure + 10)	14.5
Thurston, $\frac{1}{2} (5 \times \text{heating-surface})$	
$\frac{2}{\text{gauge pressure} + 10}$	27.3
Rankine, .006 $\times$ water evaporated per hour	21.6
Committee of U. S. Supervisors, .005 $\times$ water evaporated per hour	18

Suppose that, other data remaining the same, the draught were increased so as to burn  $13\frac{1}{2}$  lbs. coal per square foot of grate per hour, and the grate-surface cut down to 30 sq. ft. to correspond, making the coal burned per hour 400 lbs., and the water evaporated 3600 lbs., the same as before; then the English Board of Trade rule and Molesworth's rule would give an area of disk of only 15 and 24 sq. in., respectively, showing the absurdity of making the area of grate the basis of the calculation of disk area.

Another rule by Prof. Thurston is given in *American Machinist*, Dec. 1877, viz.:

$$\text{Disk area} = \frac{\frac{1}{2} \text{ max. wt. of water evap. per hour}}{\text{gauge pressure} + 10}.$$

This gives for the example considered 16.4 sq. in.

\* The edition of 1893 of the Rules of the Supervisors does not contain this rule, but gives the rule grate-surface  $\div$  2.

One rule by Rankine is 1/150 to 1/180 of the number of pounds of water evaporated per hour, equals for the above case 27 to 20 sq. in. A communication in *Power*, July, 1890, gives two other rules:

- 1st. 1 sq. in. disk area for 3 sq. ft. grate, which would give 13.3 sq. in.
- 2d. 3/4 sq. in. disk area for 1 sq. ft. grate, which would give 30 sq. in.; but if the grate-surface were reduced to 30 sq. ft. on account of increased draught, these rules would make the disk area only 10 and 22.5 sq. in., respectively.

The Philadelphia rule for 100 lbs. gauge pressure gives a disk area of 0.21 sq. in. for each sq. ft. of grate area, which would give an area of 8.4 sq. in. for 40 sq. ft. grate, and only 6.3 sq. in. if the grate is reduced to 30 sq. ft.

According to the rule this aggregate area would have to be divided between two valves. But if the boiler was driven by forced draught, then the inspector "must estimate the area of grate at 1 sq. ft. for each 16 lbs. of fuel burned per hour."

Under this condition the actual grate-surface might be cut down to  $400 \div 16 = 25$  sq. ft., and by the rule the combined area of the two safety-valves would be only  $25 \times 0.21 = 5.25$  sq. in.

Nystrom's Pocket-book, edition of 1891, gives 3/4 sq. in. for 1 sq. ft. grate; also quoting from Weisbach, vol. ii, 1/3000 of the heating-surface. This in the case considered is  $1200/3000 = .4$  sq. ft. or 57.6 sq. in.

We thus have rules which give for the area of safety-valve of the same 100-horse-power boiler results ranging all the way from 5.25 to 57.6 sq. in.

All of the rules above quoted give the area of the disk of the valve as the thing to be ascertained, and it is this area which is supposed to bear some direct ratio to the grate-surface, to the heating-surface, to the water evaporated, etc. It is difficult to see why this area has been considered even approximately proportional to these quantities, for with small lifts the area of actual opening bears a direct ratio, not to the area of disk, but to the circumference.

Thus for various diameters of valve :

Diameter .....	1	2	3	4	5	6	7
Area.....	.785	3.14	7.07	12.57	19.64	28.27	38.48
Circumference.....	3.14	6.28	9.42	12.57	15.71	18.85	21.99
Circum. $\times$ lift of 0.1 in....	.31	.63	.94	1.26	1.57	1.89	2.20
Ratio to area.....	.4	.2	.13	.1	.08	.067	.057

The apertures, therefore, are therefore directly proportional to the diameter or to the circumference, but their relation to the area is a varying one.

If the lift = 1/4 diameter, then the opening would be equal to the area of the disk, for circumference  $\times$  1/4 diameter = area, but such a lift is far beyond the actual lift of an ordinary safety-valve.

A correct rule for size of safety-valves should make the product of the diameter and the lift proportional to the weight of steam to be discharged.

A "logical" method for calculating the size of safety-valve is given in *The Locomotive*, July, 1892, based on the assumption that the actual opening should be sufficient to discharge all the steam generated by the boiler. Napier's rule for flow of steam is taken, viz., flow through aperture of one sq. in. in lbs. per second = absolute pressure  $\div$  70, or in lbs. per hour = 51.43  $\times$  absolute pressure.

If the angle of the seat is 45°, as specified in the rules of the U. S. Supervisors, the area of opening in sq. in. = circumference of the disk  $\times$  the lift  $\times$  .71, .71 being the cosine of 45°; or diameter of disk  $\times$  lift  $\times$  2.23.

A. G. Brown in his book on *The Indicator and its Practical Working* (London, 1894) gives the following as the lift of the ordinary lever safety-valve for 100 lbs. gauge-pressure:

Diam. of valve..	2	2 1/2	3	3 1/2	4	4 1/2	5	6	inches.
Rise of valve....	.0583	.0523	.0507	.0492	.0478	.0462	.0446	.0430	inch.

The lift decreases with increase of steam-pressure; thus for a 4-inch valve:  
 Abs. pressure, lbs. 45 65 85 105 115 135 155 175 195 215  
 Gauge-press., lbs.. 30 50 70 90 100 120 140 160 180 200  
 Rise, inch..... .1034 .0775 .0620 .0517 .0478 .0413 .0365 .0327 .0296 .0270

The effective area of opening Mr. Brown takes at 70% of the rise multiplied by the circumference.

An approximate formula corresponding to Mr. Brown's figures for diameters between 2 1/2 and 6 in. and gauge-pressures between 70 and 200 lbs. is

$$\text{Lift} = (.0603 - .0031d) \times \frac{115}{\text{abs. pressure}}, \text{ in which } d = \text{diam. of valve in in.}$$

If we combine this formula with the formulæ  
 Flow in lbs. per hour = area of opening in sq. in.  $\times$  51.43  $\times$  abs. pressure, and  
 Area = diameter of valve  $\times$  lift  $\times$  2.23, we obtain the following, which the  
 author suggests as probably a more correct formula for the discharging  
 capacity of the ordinary lever safety-valve than either of those above given.  
 Flow in lbs. per hour =  $d(.0603 - .0031d) \times 115 \times 2.23 \times 51.43 = d(795 - 41d)$ .  
 From which we obtain :

Diameter, inches....	1	1½	2	2½	3	3½	4	5	6	7
Flow, lbs. per hour..	754	1100	1426	1733	2016	2282	2524	2950	3294	3556
Horse-power.....	25	37	47	58	67	76	84	98	110	119

the horse-power being taken as an evaporation of 30 lbs. of water per hour.  
 If we solve the example, above given, of the boiler evaporating 3600 lbs. of  
 water per hour by this table, we find it requires one 7-inch valve, or a 2½  
 and a 3-inch valve combined. The 7-inch valve has an area of 38.5 sq. in.,  
 and the two smaller valves taken together have an area of only 12 sq. in.;  
 another evidence of the absurdity of considering the area of disk as the  
 factor which determined the capacity of the valve.

It is customary in practice not to use safety-valves of greater diameter  
 than 4 in. If a greater diameter is called for by the rule that is adopted,  
 then two or more valves are used instead of one.

**Spring-loaded Safety-valves.**—Instead of weights, springs are  
 sometimes employed to hold down safety-valves. The calculations are  
 similar to those for lever safety-valves, the tension of the spring correspond-  
 ing to a given rise being first found by experiment (see Springs, page 347).

The rules of the U. S. Supervisors allow an area of 1 sq. in. of the valve  
 to 3 sq. ft. of grate, in the case of spring-loaded valves, except in water-tube,  
 coil, or sectional boilers, in which 1 sq. in. to 6 sq. ft. of grate is allowed.

Spring-loaded safety-valves are usually of the reactionary or "pop" type,  
 in which the escape of the steam is opposed by a lip above the valve-seat,  
 against which the escaping steam reacts, causing the valve to lift higher  
 than the ordinary valve.

A. G. Brown gives the following for the rise, effective area, and quantity  
 of steam discharged per hour by valves of the "pop" or Richardson type.  
 The effective is taken at only 50% of the actual area due to the rise, on account  
 of the obstruction which the lip of the valve offers to the escape of steam.

Dia. valve, in.	1	1½	2	2½	3	3½	4	4½	5	6
Lift, inches.	.125	.150	.175	.200	.225	.250	.275	.300	.325	.375
Area, sq. in.	.196	.354	.550	.785	1.061	1.375	1.728	2.121	2.553	3.535

Gauge-pres.,	Steam discharged per hour, lbs.									
30 lbs.	474	856	1330	1897	2563	3325	4178	5128	6173	8578
50	669	1209	1878	2680	3620	4695	5901	7242	8718	12070
70	861	1556	2417	3450	4660	6144	7596	9324	11220	15535
90	1050	1897	2947	4207	5680	7370	9260	11365	13685	18945
100	1144	2065	3208	4580	6185	8322	10080	12375	14895	20625
120	1332	2405	3736	5332	7202	9342	11735	14410	17340	24015
140	1516	2738	4254	6070	8200	10635	13365	16405	19745	27340
160	1696	3064	4760	6794	9175	11900	14955	18355	22095	30595
180	1883	3400	5283	7540	10180	13250	16595	20370	24520	33950
200	2062	3724	5786	8258	11150	14465	18175	22310	26855	37185

If we take 30 lbs. of steam per hour, at 100 lbs. gauge-pressure = 1 H.P.,  
 we have from the above table:

Diameter, inches....	1	1½	2	2½	3	3½	4	4½	5	6
Horse-power.....	38	69	107	153	206	277	336	412	496	687

A safety-valve should be capable of discharging a much greater quantity  
 of steam than that corresponding to the rated horse-power of a boiler, since  
 a boiler having ample grate surface and strong draught may generate more  
 than double the quantity of steam its rating calls for.

The Consolidated Safety-valve Co.'s circular gives the following rated  
 capacity of its nickel-seat "pop" safety-valves:

Size, in.....	1	1¼	1½	2	2½	3	3½	4	4½	5	5½
Boiler { from	8	10	20	35	60	75	100	125	150	175	200
H.P. { to	10	15	30	50	75	100	125	150	175	200	275

The figures in the lower line from 2 inch to 5 inch, inclusive, correspond to  
 the formula H.P. = 50(diameter - 1 inch).

**THE INJECTOR.**

**Equation of the Injector.**

- Let *S* be the number of pounds of steam used;
- W* the number of pounds of water lifted and forced into the boiler;
- h* the height in feet of a column of water, equivalent to the absolute pressure in the boiler;
- h*<sub>0</sub> the height in feet the water is lifted to the injector;
- t*<sub>1</sub> the temperature of the water before it enters the injector;
- t*<sub>2</sub> the temperature of the water after leaving the injector;
- H* the total heat above 32° F. in one pound of steam in the boiler, in heat-units;
- L* the lost work in friction and the equivalent lost work due to radiation and lost heat;
- 778 the mechanical equivalent of heat.

Then

$$S[H - (t_2 - 32^\circ)] = W(t_2 - t_1) + \frac{(W + S)h + Wh_0 + L}{778}$$

An equivalent formula, neglecting *Wh*<sub>0</sub> + *L* as small, is

$$S = \left[ W(t_2 - t_1) + \frac{W + S}{d} \cdot p \cdot \frac{144}{778} \right] \frac{1}{H - (t_2 - 32^\circ)}$$

$$\text{or } S = \frac{W[(t_2 - t_1)d + .1851p]}{[H - (t_2 - 32^\circ)]d - .1851p}$$

in which *d* = weight of 1 cu. ft. of water at temperature *t*<sub>2</sub>; *p* = absolute pressure of steam, lbs. per sq. in.

The rule for finding the proper sectional area for the narrowest part of the nozzles is given as follows by Rankine, S. E. p. 477:

$$\text{Area in square inches} = \frac{\text{cubic feet per hour gross feed-water.}}{800 \sqrt{\text{pressure in atmospheres}}}$$

An important condition which must be fulfilled in order that the injector will work is that the supply of water must be sufficient to condense the steam. As the temperature of the supply or feed-water is higher, the amount of water required for condensing purposes will be greater.

The table below gives the calculated value of the maximum ratio of water to the steam, and the values obtained on actual trial, also the highest admissible temperature of the feed-water as shown by theory and the highest actually found by trial with several injectors.

Gauge-pressure, pounds per sq. in.	MAXIMUM RATIO WATER TO STEAM.			Gauge-pressure, pounds per sq. in.	MAXIMUM TEMPERATURE OF FEED-WATER.

H, Hancock inspirator; P, Park injector; M, Metropolitan injector; S, Sellers 1876 injector.

**Efficiency of the Injector.**—Experiments at Cornell University, described by Prof. R. C. Carpenter, in *Cassier's Magazine*, Feb. 1892, show that the injector, when considered merely as a pump, has an exceedingly low efficiency, the duty ranging from 161,000 to 2,752,000 under different circumstances of steam and delivery pressure. Small direct-acting pumps, such as are used for feeding boilers, show a duty of from 4 to 8 million lbs., and the best pumping-engines from 100 to 140 million. When used for feeding water into a boiler, however, the injector has a thermal efficiency of 100%, less the trifling loss due to radiation, since all the heat rejected passes into the water which is carried into the boiler.

The loss of work in the injector due to friction reappears as heat which is carried into the boiler, and the heat which is converted into useful work in the injector appears in the boiler as stored-up energy.

Although the injector thus has a perfect efficiency as a boiler-feeder, it is nevertheless not the most economical means for feeding a boiler, since it can draw only cold or moderately warm water, while a pump can feed water which has been heated by exhaust steam which would otherwise be wasted.

**Performance of Injectors.**—In *Am. Mach.*, April 13, 1893, are a number of letters from different manufacturers of injectors in reply to the question: "What is the best performance of the injector in raising or lifting water to any height?" Some of the replies are tabulated below.

W. Sellers & Co.—25.51 lbs. water delivered to boiler per lb. of steam; temperature of water, 64°; steam pressure, 65 lbs.

Schaeffer & Budenberg—1 gal. water delivered to boiler for 0.4 to 0.8 lb. steam.

Injector will lift by suction water of . . . . .  
   140° F.    136° to 133°    122° to 118°    113° to 107°  
 If boiler pressure is. 30 to 60 lbs.    60 to 90 lbs.    90 to 120 lbs.    120 to 150 lbs.

If the water is not over 80° F., the injector will force against a pressure 75 lbs. higher than that of the steam.

Hancock Inspirator Co.:

Lift in feet.....	22	22	22	11
Boiler pressure, absolute, lbs.....	75.8	54.1	95.5	75.4
Temperature of suction.....	34.9°	35.4°	47.3°	53.2°
Temperature of delivery.....	134°	117.4°	173.7°	131.1
Water fed per lb. of steam, lbs....	11.02	13.67	8.18	13.3

The theory of the injector is discussed in Wood's, Peabody's, and Rontgen's treatises on Thermodynamics. See also "Theory and Practice of the Injector," by Strickland L. Kneass, New York, 1895.

**Boiler-feeding Pumps.**—Since the direct-acting pump, commonly used for feeding boilers, has a very low efficiency, or less than one tenth that of a good engine, it is generally better to use a pump driven by belt from the main engine or driving shaft. The mechanical work needed to feed a boiler may be estimated as follows: If the combination of boiler and engine is such that half a cubic foot, say 32 lbs. of water, is needed per horsepower, and the boiler-pressure is 100 lbs. per sq. in., then the work of feeding the quantity of water is 100 lbs.  $\times$  144 sq. in.  $\times$   $\frac{1}{2}$  ft.-lbs. per hour = 120 ft.-lbs. per min. =  $120/33,000 = .0036$  H.P., or less than  $4/10$  of  $1\%$  of the power exerted by the engine. If a direct-acting pump, which discharges its exhaust steam into the atmosphere, is used for feeding, and it has only  $1/10$  the efficiency of the main engine, then the steam used by the pump will be equal to nearly 4% of that generated by the boiler.

The following table by Prof. D. S. Jacobus gives the relative efficiency of steam and power pumps and injector, with and without heater, as used upon a boiler with 80 lbs. gauge-pressure, the pump having a duty of 10,000,000 ft.-lbs. per 100 lbs. of coal when no heater is used; the injector heating the water from 60° to 150° F.

Direct-acting pump feeding water at 60°, without a heater.....	1.000
Injector feeding water at 150°, without a heater.....	.985
Injector feeding water through a heater in which it is heated from 150° to 200°.....	.938
Direct-acting pump feeding water through a heater, in which it is heated from 60° to 200°.....	.879
Geared pump, run from the engine, feeding water through a heater, in which it is heated from 60° to 200°.....	.863

**FEED-WATER HEATERS.**

**Percentage of Saving for Each Degree of Increase in Temperature of Feed-water Heated by Waste Steam.**

Initial Temp. of Feed.	Pressure of Steam in Boiler, lbs. per sq. in. above Atmosphere.											Initial Temp.

An approximate rule for the conditions of ordinary practice is a saving of 1% is made by each increase of 11° in the temperature of the feed-water. This corresponds to .0909% per degree.

The calculation of saving is made as follows: Boiler-pressure, 100 lbs. gauge; total heat in steam above 32° = 1185 B.T.U. Feed-water, original temperature 60°, final temperature 209° F. Increase in heat-units, 150. Heat-units above 32° in feed-water of original temperature = 28. Heat-units in steam above that in cold feed-water, 1185 - 28 = 1157. Saving by the feed-water heater = 150/1157 = 12.96%. The same result is obtained by the use of the table. Increase in temperature 150° × tabular figure .0864 = 12.96%. Let total heat of 1 lb. of steam at the boiler-pressure =  $H$ ; total heat of 1 lb. of feed-water before entering the heater =  $h_1$ , and after passing through the heater =  $h_2$ ; then the saving made by the heater is  $\frac{h_2 - h_1}{H - h_1}$ .

**Strains Caused by Cold Feed-water.**—A calculation is made in *The Locomotive* of March, 1893, of the possible strains caused in the section of the shell of a boiler by cooling it by the injection of cold feed-water. Assuming the plate to be cooled 200° F., and the coefficient of expansion of steel to be .0000067 per degree, a strip 10 in. long would contract .013 in., if it were free to contract. To resist this contraction, assuming that the strip is firmly held at the ends and that the modulus of elasticity is 29,000,000, would require a force of 37,700 lbs. per sq. in. Of course this amount of strain cannot actually take place, since the strip is not firmly held at the ends, but is allowed to contract to some extent by the elasticity of the surrounding metal. But, says *The Locomotive*, we may feel pretty confident that in the case considered a longitudinal strain of somewhere in the neighborhood of 8000 or 10,000 lbs. per sq. in. may be produced by the feed-water striking directly upon the plates; and this, in addition to the normal strain produced by the steam-pressure, is quite enough to tax the girth-seams beyond their elastic limit, if the feed-pipe discharges anywhere near them. Hence it is not surprising that the girth-seams develop leaks and cracks in 99 cases out of every 100 in which the feed discharges directly upon the fire-sheets.

### STEAM SEPARATORS.

If moist steam flowing at a high velocity in a pipe has its direction suddenly changed, the particles of water are by their momentum projected in their original direction against the bend in the pipe or wall of the chamber in which the change of direction takes place. By making proper provision for drawing off the water thus separated the steam may be dried to a greater or less extent.

For long steam-pipes a large drum should be provided near the engine for trapping the water condensed in the pipe. A drum 3 feet diameter, 15 feet high, has given good results in separating the water of condensation of a steam-pipe 10 inches diameter and 800 feet long.

**Efficiency of Steam Separators.**—Prof. R. C. Carpenter, in 1891, made a series of tests of six steam separators, furnishing them with steam containing different percentages of moisture, and testing the quality of steam before entering and after passing the separator. A condensed table of the principal results is given below.

Make of Separator.	Test with Steam of about 10% of Moisture.			Tests with Varying Moisture.		
	Quality of Steam before.	Quality of Steam after.	Efficiency per cent.	Quality of Steam before.	Quality of Steam after.	Av'ge Efficiency.
B	87.0%	98.8%	90.8	66.1 to 97.5%	97.8 to 99%	87.6
A	90.1	98.0	80.0	51.9 " 98	97.9 " 99.1	76.4
D	89.6	95.3	59.6	72.2 " 96.1	95.5 " 98.2	71.7
C	90.6	93.7	33.0	67.1 " 96.8	93.7 " 98.4	63.4
E	88.4	90.2	15.5	68.6 " 98.1	79.3 " 98.5	36.9
F	88.9	92.1	28.8	70.4 " 97.7	84.1 " 97.9	28.4

Conclusions from the tests were: 1. That no relation existed between the volume of the several separators and their efficiency.

2. No marked decrease in pressure was shown by any of the separators, the most being 1.7 lbs. in E.

3. Although changed direction, reduced velocity, and perhaps centrifugal force are necessary for good separation, still some means must be provided to lead the water out of the current of the steam.

The high efficiency obtained from B and A was largely due to this feature. In B the interior surfaces are corrugated and thus catch the water thrown out of the steam and readily lead it to the bottom.

In A, as soon as the water falls or is precipitated from the steam, it comes in contact with the perforated diaphragm through which it runs into the space below, where it is not subjected to the action of the steam.

Experiments made by Prof. Carpenter on a "Stratton" separator in 1894 showed that the moisture in the steam leaving the separator was less than 1% when that in the steam supplied ranged from 6% to 21%.

### DETERMINATION OF THE MOISTURE IN STEAM—STEAM CALORIMETERS.

In all boiler-tests it is important to ascertain the quality of the steam, i.e., 1st, whether the steam is "saturated" or contains the quantity of heat due to the pressure according to standard experiments; 2d, whether the quantity of heat is deficient, so that the steam is wet; and 3d, whether the heat is in excess and the steam superheated. The best method of ascertaining the quality of the steam is undoubtedly that employed by a committee which tested the boilers at the American Institute Exhibition of 1871-2, of which Prof. Thurston was chairman, i.e., condensing all the water evaporated by the boiler by means of a surface condenser, weighing the condensing water, and taking its temperature as it enters and as it leaves the condenser; but this plan cannot always be adopted.

A substitute for this method is the barrel calorimeter, which with careful operation and fairly accurate instruments may generally be relied on to give results within two per cent of accuracy (that is, a sample of steam which gives the apparent result of 2% of moisture may contain anywhere between 0 and 4%). This calorimeter is described as follows: A sample of the steam is taken by inserting a perforated  $\frac{1}{2}$ -inch pipe into and through the main pipe near the boiler, and led by a hose, thoroughly felted, to a barrel, holding preferably 400 lbs. of water, which is set upon a platform scale and

provided with a cock or valve for allowing the water to flow to waste, and with a small propeller for stirring the water.

To operate the calorimeter the barrel is filled with water, the weight and temperature ascertained, steam blown through the hose outside the barrel until the pipe is thoroughly warmed, when the hose is suddenly thrust into the water, and the propeller operated until the temperature of the water is increased to the desired point, say about 110° usually. The hose is then withdrawn quickly, the temperature noted, and the weight again taken.

An error of 1/10 of a pound in weighing the condensed steam, or an error of 1/2 degree in the temperature, will cause an error of over 1% in the calculated percentage of moisture. See *Trans. A. S. M. E.*, vi. 293.

The calculation of the percentage of moisture is made as below:

$$Q = \frac{1}{H - T} \left[ \frac{W}{w} (h_1 - h) - (T - h_1) \right].$$

$Q$  = quality of the steam, dry saturated steam being unity.

$H$  = total heat of 1 lb. of steam at the observed pressure.

$T$  = " " " " " water at the temperature of steam of the observed pressure.

$h$  = " " " " " condensing water, original.

$h_1$  = " " " " " " " final.

$W$  = weight of condensing water, corrected for water-equivalent of the apparatus.

$w$  = weight of the steam condensed.

Percentage of moisture =  $1 - Q$ .

If  $Q$  is greater than unity, the steam is superheated, and the degrees of superheating =  $2.0833 (H - T) (Q - 1)$ .

**Difficulty of Obtaining a Correct Sample.**—Recent experiments by Prof. D. S. Jacobus, *Trans. A. S. M. E.*, xvi. 1017, show that it is practically impossible to obtain a true average sample of the steam flowing in a pipe. For accurate determinations all the steam made by the boiler should be passed through a separator, the water separated should be weighed, and a calorimeter test made of the steam just after it has passed the separator.

**Coil Calorimeters.**—Instead of the open barrel in which the steam is condensed, a coil acting as a surface-condenser may be used, which is placed in the barrel, the water in coil and barrel being weighed separately. For description of an apparatus of this kind designed by the author, which he has found to give results with a probable error not exceeding 1/2 per cent of moisture, see *Trans. A. S. M. E.*, vi. 294. This calorimeter may be used continuously, if desired, instead of intermittently. In this case a continuous flow of condensing water into and out of the barrel must be established, and the temperature of inflow and outflow and of the condensed steam read at short intervals of time.

**Throttling Calorimeter.**—For percentages of moisture not exceeding 3 per cent the throttling calorimeter is most useful and convenient and remarkably accurate. In this instrument the steam which reaches it in a 1/2-inch pipe is throttled by an orifice 1/16 inch diameter, opening into a chamber which has an outlet to the atmosphere. The steam in this chamber has its pressure reduced nearly or quite to the pressure of the atmosphere, but the total heat in the steam before throttling causes the steam in the chamber to be superheated more or less according to whether the steam before throttling was dry or contained moisture. The only observations required are those of the temperature and pressure of the steam on each side of the orifice.

The author's formula for reducing the observations of the throttling calorimeter is as follows (*Experiments on Throttling Calorimeters, Am. Mach.*, Aug. 4, 1892):

$$w = 100 \times \frac{H - h - K(T - t)}{L}, \text{ in which } w = \text{percent-}$$

age of moisture in the steam;  $H$  = total heat, and  $L$  = latent heat of steam in the main pipe;  $h$  = total heat due the pressure in the discharge side of the calorimeter, = 1146.6 at atmospheric pressure;  $K$  = specific heat of superheated steam;  $T$  = temperature of the throttled and superheated steam in the calorimeter;  $t$  = temperature due the pressure in the calorimeter, = 212° at atmospheric pressure.

Taking  $K$  at 0.48 and the pressure in the discharge side of the calorimeter as atmospheric pressure, the formula becomes

$$w = 100 \times \frac{H - 1146.6 - 0.48(T - 212^\circ)}{L}.$$

From this formula the following table is calculated :

## MOISTURE IN STEAM—DETERMINATIONS BY THROTTLING CALORIMETER.

Degree of Super-heating $T - 212^{\circ}$ .	Gauge-pressures.

**Separating Calorimeters.**—For percentages of moisture beyond the range of the throttling calorimeter the separating calorimeter is used, which is simply a steam separator on a small scale. An improved form of this calorimeter is described by Prof. Carpenter in *Power*, Feb. 1893.

For fuller information on various kinds of calorimeters, see papers by Prof. Peabody, Prof. Carpenter, and Mr. Barrus in *Trans. A. S. M. E.*, vols. x, xi, xii, 1889 to 1891; Appendix to Report of Com. on Boiler Tests, *A. S. M. E.*, vol. vi, 1884; Circular of Schaeffer & Budenberg, N. Y., "Calorimeters, Throttling and Separating," 1894.

**Identification of Dry Steam by Appearance of a Jet.**—Prof. Denton (*Trans. A. S. M. E.*, vol. x.) found that jets of steam show unmistakable change of appearance to the eye when steam varies less than 1% from the condition of saturation either in the direction of wetness or superheating.

If a jet of steam flow from a boiler into the atmosphere under circumstances such that very little loss of heat occurs through radiation, etc., and the jet be transparent close to the orifice, or be even a grayish-white color, the steam may be assumed to be so nearly dry that no portable condensing calorimeter will be capable of measuring the amount of water in the steam. If the jet be strongly white, the amount of water may be roughly judged up to about 2%, but beyond this a calorimeter only can determine the exact amount of moisture.

A common brass pet-cock may be used as an orifice, but it should, if possible, be set into the steam-drum of the boiler and never be placed further away from the latter than 4 feet, and then only when the intermediate reservoir or pipe is well covered.

• **Usual Amount of Moisture in Steam Escaping from a Boiler.**—In the common forms of horizontal tubular land boilers and water-tube boilers with ample horizontal drums, and supplied with water free from substances likely to cause foaming, the moisture in the steam does not generally exceed 2% unless the boiler is overdriven or the water-level is carried too high.

CHIMNEYS.

**Chimney Draught Theory.**—The commonly accepted theory of chimney draught, based on Peclet's and Rankine's hypotheses (see Rankine, S. E.), is discussed by Prof. De Volson Wood in Trans. A. S. M. E., vol. xi.

Peclet represented the law of draught by the formula

$$h = \frac{u^2}{2g} \left( 1 + G + \frac{fl}{m} \right),$$

in which *h* is the "head," defined as such a height of hot gases as, if added to the column of gases in the chimney, would produce the same pressure at the furnace as a column of outside air, of the same area of base, and a height equal to that of the chimney;

*u* is the required velocity of gases in the chimney;

*G* a constant to represent the resistance to the passage of air through the coal;

*l* the length of the flues and chimney;

*m* the mean hydraulic depth or the area of a cross-section divided by the perimeter;

*f* a constant depending upon the nature of the surfaces over which the gases pass, whether smooth, or sooty and rough.

Rankine's formula (Steam Engine, p. 288), derived by giving certain values to the constants (so-called) in Peclet's formula, is

$$h = \frac{\tau_0 \left( 0.0807 \right)}{\tau_2} H - H = \left( 0.96 \frac{\tau_1}{\tau_2} - 1 \right) H;$$

$$\frac{\tau_0 \left( 0.084 \right)}{\tau_1}$$

in which *H* = the height of the chimney in feet;

$\tau_0$  = 493° F., absolute (temperature of melting ice);

$\tau_1$  = absolute temperature of the gases in the chimney;

$\tau_2$  = absolute temperature of the external air.

Prof. Wood derives from this a still more complex formula which gives the height of chimney required for burning a given quantity of coal per second, and from it he calculates the following table, showing the height of chimney required to burn respectively 24, 20, and 16 lbs. of coal per square foot of grate per hour, for the several temperatures of the chimney gases given.

Outside Air. $\tau_2$	Chimney Gas.		Coal per sq. ft. of grate per hour, lbs.		
	$\tau_1$ Absolute.	Temp. Fahr.	24	20	16
			Height <i>H</i> , feet.		
520°	700	239	250.9	157.6	67.8
absolute or	800	339	172.4	115.8	55.7
59° F.	1000	539	149.1	100.0	48.7
	1100	639	148.8	98.9	48.2
	1200	739	152.0	100.9	49.1
	1400	939	159.9	105.7	51.2
	1600	1139	168.8	111.0	53.5
	2000	1539	206.5	132.2	63.0

Rankine's formula gives a maximum draught when  $\tau = 2 \frac{1}{12} \tau_2$ , or 622° F., when the outside temperature is 60°. Prof. Wood says: "This result is not a fixed value, but departures from theory in practice do not affect the result largely. There is, then, in a properly constructed chimney, properly working, a temperature giving a maximum draught,\* and that temperature is not far from the value given by Rankine, although in special cases it may be 50° or 75° more or less."

All attempts to base a practical formula for chimneys upon the theoretical formula of Peclet and Rankine have failed on account of the impossibility of assigning correct values to the so-called "constants"  $G$  and  $f$ . (See Trans. A. S. M. E., xi. 984.)

**Force or Intensity of Draught.**—The force of the draught is equal to the difference between the weight of the column of hot gases inside of the chimney and the weight of a column of the external air of the same height. It is measured by a draught-gauge, usually a U-tube partly filled with water, one leg connected by a pipe to the interior of the flue, and the other open to the external air.

If  $D$  is the density of the air outside,  $d$  the density of the hot gas inside, in lbs. per cubic foot,  $h$  the height of the chimney in feet, and .192 the factor for converting pressure in lbs. per sq. ft. into inches of water column, then the formula for the force of draught expressed in inches of water is,

$$F = .192h(D - d).$$

The density varies with the absolute temperature (see Rankine).

$$d = \frac{\tau_0}{\tau_1} 0.084; \quad D = 0.0807 \frac{\tau_0}{\tau_2},$$

where  $\tau_0$  is the absolute temperature at 32° F., = 493.,  $\tau_1$  the absolute temperature of the chimney gases and  $\tau_2$  that of the external air. Substituting these values the formula for force of draught becomes

$$F = .192h \left( \frac{39.79}{\tau_2} - \frac{41.41}{\tau_1} \right) = h \left( \frac{7.64}{\tau_2} - \frac{7.95}{\tau_1} \right).$$

To find the maximum intensity of draught for any given chimney, the heated column being 600° F., and the external air 60°, multiply the height above grate in feet by .0073, and the product is the draught in inches of water.

**Height of Water Column Due to Unbalanced Pressure in Chimney 100 Feet High.** (*The Locomotive*, 1884.)

Temp. in the Chimney.	Temperature of the External Air—Barometer, 14.7 lbs. per sq. in.

\* Much confusion to students of the theory of chimneys has resulted from their understanding the words maximum draught to mean maximum intensity or pressure of draught, as measured by a draught-gauge. It here means maximum quantity or weight of gases passed up the chimney. The maximum intensity is found only with maximum temperature, but after the temperature reaches about 622° F. the density of the gas decreases more rapidly than its velocity increases, so that the weight is a maximum about 622° F., as shown by Rankine.—W. K.

For any other height of chimney than 100 ft. the height of water-column is found by simple proportion, the height of water column being directly proportioned to the height of chimney.

The calculations have been made for a chimney 100 ft. high, with various temperatures outside and inside of the flue, and on the supposition that the temperature of the chimney is uniform from top to bottom. This is the basis on which all calculations respecting the draught-power of chimneys have been made by Rankine and other writers, but it is very far from the truth in most cases. The difference will be shown by comparing the reading of the draught-gauge with the table given. In one case a chimney 122 ft. high showed a temperature at the base of 320°, and at the top of 230°.

Box, in his "Treatise on Heat," gives the following table:

DRAUGHT POWERS OF CHIMNEYS, ETC., WITH THE INTERNAL AIR AT 552°, AND THE EXTERNAL AIR AT 62°, AND WITH THE DAMPER NEARLY CLOSED.

Height of Chimney in feet.	Draught Power in ins. of water.	Theoretical Velocity in feet per second.		Height of Chimney in feet.	Draught Power in ins. of water.	Theoretical Velocity in feet per second.	
		Cold Air Entering.	Hot Air at Exit.			Cold Air Entering.	Hot Air at Exit.

**Rate of Combustion Due to Height of Chimney.—**

Trowbridge's "Heat and Heat Engines" gives the following table showing the heights of chimney for producing certain rates of combustion per sq. ft. of section of the chimney. It may be approximately true for anthracite in moderate and large sizes, but greater heights than are given in the table are needed to secure the given rates of combustion with small sizes of anthracite, and for bituminous coal smaller heights will suffice if the coal is reasonably free from ash—5% or less.

Heights in feet.	Lbs. of Coal Burned per Hour per Sq. Ft. of Section of Chimney.	Lbs. of Coal Burned per Sq. Ft. of Grate, the Ratio of Grate to Section of Chimney being 8 to 1.	Heights in feet.	Lbs. of Coal Burned per Hour per Sq. Ft. of Section of Chimney.	Lbs. of Coal Burned per Sq. Ft. of Grate, the Ratio of Grate to Section of Chimney being 8 to 1.
20	60	7.5	70	126	15.8
25	68	8.5	75	131	16.4
30	76	9.5	80	135	16.9
35	84	10.5	85	139	17.4
40	93	11.6	90	144	18.0
45	99	12.4	95	148	18.5
50	105	13.1	100	152	19.0
55	111	13.8	105	156	19.5
60	116	14.5	110	160	20.0
65	121	15.1			

Thurston's rule for rate of combustion effected by a given height of chimney (Trans. A. S. M. E., xi. 991) is: Subtract 1 from twice the square root of the height, and the result is the rate of combustion in pounds per square foot of grate per hour, for anthracite. Or rate =  $2\sqrt{h} - 1$ , in which  $h$  is the height in feet. This rule gives the following:

$h$	50	60	70	80	90	100	110	125	150	175	200
$2\sqrt{h} - 1$	13.14	14.49	15.73	16.89	17.97	19	19.97	21.36	23.49	25.45	27.28

The results agree closely with Trowbridge's table given above. In prac-

tice the high rates of combustion for high chimneys given by the formula are not generally obtained, for the reason that with high chimneys there are usually long horizontal flues, serving many boilers, and the friction and the interference of currents from the several boilers are apt to cause the intensity of draught in the branch flues leading to each boiler to be much less than that at the base of the chimney. The draught of each boiler is also usually restricted by a damper and by bends in the gas-passages. In a battery of several boilers connected to a chimney 150 ft. high, the author found a draught of  $\frac{3}{4}$ -inch water-column at the boiler nearest the chimney, and only  $\frac{1}{4}$ -inch at the boiler farthest away. The first boiler was wasting fuel from too high temperature of the chimney-gases, 900°, having too large a grate-surface for the draught, and the last boiler was working below its rated capacity and with poor economy, on account of insufficient draught.

The effect of changing the length of the flue leading into a chimney 60 ft. high and 2 ft. 9 in. square is given in the following table, from Box on "Heat":

Length of Flue in feet.	Horse-power.	Length of Flue in feet.	Horse-power.
50	107.6	800	56.1
100	100.0	1,000	51.4
200	85.3	1,500	43.3
400	70.8	2,000	38.2
600	62.5	3,000	31.7

The temperature of the gases in this chimney was assumed to be 552° F., and that of the atmosphere 62°.

**High Chimneys not Necessary.**—Chimneys above 150 ft. in height are very costly, and their increased cost is rarely justified by increased efficiency. In recent practice it has become somewhat common to build two or more smaller chimneys instead of one large one. A notable example is the Spreckels Sugar Refinery in Philadelphia, where three separate chimneys are used for one boiler-plant of 7500 H.P. The three chimneys are said to have cost several thousand dollars less than a single chimney of their combined capacity would have cost. Very tall chimneys have been characterized by one writer as "monuments to the folly of their builders."

**Heights of Chimney required for Different Fuels.**—The minimum height necessary varies with the fuel, wood requiring the least, then good bituminous coal, and fine sizes of anthracite the greatest. It also varies with the character of the boiler—the smaller and more circuitous the gas-passages the higher the stack required; also with the number of boilers, a single boiler requiring less height than several that discharge into a horizontal flue. No general rule can be given.

### SIZE OF CHIMNEYS.

The formula given below, and the table calculated therefrom for chimneys up to 96 in. diameter and 200 ft. high, were first published by the author in 1884 (Trans. A. S. M. E. vi., 81). They have met with much approval since that date by engineers who have used them, and have been frequently published in boiler-makers' catalogues and elsewhere. The table is now extended to cover chimneys up to 12 ft. diameter and 300 ft. high. The sizes corresponding to the given commercial horse-powers are believed to be ample for all cases in which the draught areas through the boiler-flues and connections are sufficient, say not less than 20% greater than the area of the chimney, and in which the draught between the boilers and chimney is not checked by long horizontal passages and right-angled bends.

*Note that the figures in the table correspond to a coal consumption of 5 lbs. of coal per horse-power per hour.* This liberal allowance is made to cover the contingencies of poor coal being used, and of the boilers being driven beyond their rated capacity. In large plants, with economical boilers and engines, good fuel and other favorable conditions, which will reduce the maximum rate of coal consumption at any one time to less than 5 lbs. per H. P. per hour, the figures in the table may be multiplied by the ratio of 5 to the maximum expected coal consumption per H.P. per hour. Thus, with conditions which make the maximum coal consumption only 2.5 lbs. per hour, the chimney 300 ft. high  $\times$  12 ft. diameter should be sufficient for  $6155 \times 2 = 12,310$  horse-power. The formula is based on the following data:

1. The draught power of the chimney varies as the square root of the height.

2. The retarding of the ascending gases by friction may be considered as equivalent to a diminution of the area of the chimney, or to a lining of the chimney by a layer of gas which has no velocity. The thickness of this lining is assumed to be 2 inches for all chimneys, or the diminution of area equal to the perimeter  $\times$  2 inches (neglecting the overlapping of the corners of the lining). Let  $D$  = diameter in feet,  $A$  = area, and  $E$  = effective area in square feet.

$$\text{For square chimneys, } E = D^2 - \frac{8D}{12} = A - \frac{2}{3} \sqrt{A}.$$

$$\text{For round chimneys, } E = \frac{\pi}{4} \left( D^2 - \frac{8D}{12} \right) = A - 0.591 \sqrt{A}.$$

For simplifying calculations, the coefficient of  $\sqrt{A}$  may be taken as 0.6 for both square and round chimneys, and the formula becomes

$$E = A - 0.6 \sqrt{A}.$$

3. The power varies directly as this effective area  $E$ .

4. A chimney should be proportioned so as to be capable of giving sufficient draught to cause the boiler to develop much more than its rated power, in case of emergencies, or to cause the combustion of 5 lbs. of fuel per rated horse-power of boiler per hour.

5. The power of the chimney varying directly as the effective area,  $E$ , and as the square root of the height,  $H$ , the formula for horse-power of boiler for a given size of chimney will take the form  $H.P. = CE \sqrt{H}$ , in which  $C$  is a constant, the average value of which, obtained by plotting the results obtained from numerous examples in practice, the author finds to be 3.33.

The formula for horse-power then is

$$H.P. = 3.33E \sqrt{H}, \text{ or } H.P. = 3.33(A - .6 \sqrt{A}) \sqrt{H}.$$

If the horse-power of boiler is given, to find the size of chimney, the height being assumed,

$$E = 0.3 \text{ H.P.} \div \sqrt{H}; = A - 0.6 \sqrt{A}.$$

For round chimneys, diameter of chimney = diam. of  $E + 4''$ .

For square chimneys, side of chimney =  $\sqrt{E} + 4''$ .

If effective area  $E$  is taken in square feet, the diameter in inches is  $d = 13.54 \sqrt{E} + 4''$ , and the side of a square chimney in inches is  $s = 12 \sqrt{E} + 4''$ .

If horse-power is given and area assumed, the height  $H = \left( \frac{0.3 \text{ H.P.}}{E} \right)^2$ .

In proportioning chimneys the height is generally first assumed, with due consideration to the heights of surrounding buildings or hills near to the proposed chimney, the length of horizontal flues, the character of coal to be used, etc., and then the diameter required for the assumed height and horse-power is calculated by the formula or taken from the table.

An approximate formula for chimneys above 1000 H.P. is  $H.P. = 2\frac{1}{2} D^2 \sqrt{H}$ . This gives the H.P. somewhat greater than the figures in the table.

### The Protection of Tall Chimney-shafts from Lightning.

—C. Molyneux and J. M. Wood (*Industries*, March 28, 1890) recommend for tall chimneys the use of a coronal or heavy band at the top of the chimney, with copper points 1 ft. in height at intervals of 2 ft. throughout the circumference. The points should be gilded to prevent oxidation. The most approved form of conductor is a copper tape about  $\frac{3}{4}$  in. by  $\frac{1}{8}$  in. thick, weighing 6 ozs. per ft. If iron is used it should weigh not less than  $2\frac{1}{4}$  lbs. per ft. There must be no insulation, and the copper tape should be fastened to the chimney with holdfasts of the same material, to prevent voltaic action. An allowance for expansion and contraction should be made, say 1 in. in 40 ft. Slight bends in the tape, not too abrupt, answer the purpose. For an earth terminal a plate of metal at least 3 ft. sq. and  $\frac{1}{16}$  in. thick should be buried as deep as possible in a damp spot. The plate should be of the same metal as the conductor, to which it should be soldered. The best earth terminal is water, and when a deep well or other large body of water is at hand, the conductor should be carried down into it. Right-angled bends in the conductor should be avoided. No bend in it should be over  $30^\circ$ .

NOTES ON THE ABOVE CHIMNEYS.—1. This chimney is situated near Freiberg, on the right bank of the Mulde, at an elevation of 219 feet above that of the foundry works, so that its total height above the sea will be 711¾ feet. The works are situated on the bank of the river, and the furnace-gases are conveyed across the river to the chimney on a bridge, through a pipe 3227 feet in length. It is built throughout of brick, and will cost about \$40,000.—*Mfr. and Bldr.*

2. Owing to the fact that it was struck by lightning, and somewhat damaged, as a precautionary measure a copper extension subsequently was added to it, making its entire height 488 feet.

1, 2, 3, and 4 were built of these great heights to remove deleterious gases from the neighborhood, as well as for draught for boilers.

5. The structure rests on a solid granite foundation, 55 x 30 feet, and 16 feet deep. In its construction there were used 1,700,000 bricks, 2000 tons of stone, 2000 barrels of mortar, 1000 loads of sand, 1000 barrels of Portland cement, and the estimated cost is \$40,000. It is arranged for two flues, 9 feet 6 inches by 6 feet, connecting with 40 boilers, which are to be run in connection with four triple-expansion engines of 1350 horse-power each.

6. It has a uniform batter of 2.85 inches to every 10 feet. Designed for 21 boilers of 200 H. P. each. It is surmounted by a cast-iron coping which weighs six tons, and is composed of thirty-two sections, which are bolted together by inside flanges, so as to present a smooth exterior. The foundation is in concrete, composed of crushed limestone 6 parts, sand 3 parts, and Portland cement 1 part. It is 40 feet square and 5 feet deep. Two qualities of brick were used; the outer portions were of the first quality North River, and the backing up was of good quality New Jersey brick. Every twenty feet in vertical measurement an iron ring, 4 inches wide and ¾ to ½ inch thick, placed edgewise, was built into the walls about 8 inches from the outer circle. As the chimney starts from the base it is double. The outer wall is 5 feet 2 inches in thickness, and inside of this is a second wall 20 inches thick and spaced off about 20 inches from main wall. From the interior surface of the main wall eight buttresses are carried, nearly touching this inner or main flue wall in order to keep it in line should it tend to sag. The interior wall, starting with the thickness described, is gradually reduced until a height of about 90 feet is reached, when it is diminished to 8 inches. At 165 feet it ceases,

and the rest of the chimney is without lining. The total weight of the chimney and foundation is 5000 tons. It was completed in September, 1888.

7. Connected to 12 boilers, with 1200 square feet of grate-surface. Draught-gauge 1 9/16 inches.

8. Connected to 8 boilers, 6' 8" diameter  $\times$  18 feet. Grate-surface 448 square feet.

9. Connected to 64 Manning vertical boilers, total grate surface 1810 sq. ft. Designed to burn 18,000 lbs. anthracite per hour.

10. Designed for 12,000 H.P. of engines; (compound condensing).

11. Grate-surface 434 square feet; H.P. of boilers (Galloway) about 2500.

13. Eight boilers (water-tube) each 450 H.P.; 12 engines, each 300 H.P. Plant designed for 36,000 incandescent lights. For the first 60 feet the exterior wall is 28 inches thick, then 24 inches for 20 feet, 20 inches for 30 feet, 16 inches for 20 feet, and 12 inches for 20 feet. The interior wall is 9 inches thick of fire-brick for 50 feet, and then 8 inches thick of red brick for the next 30 feet. Illustrated in *Iron Age*, January 2, 1890.

A number of the above chimneys are illustrated in *Power*, Dec., 1890.

Chimney at Knoxville, Tenn., illustrated in *Eng'g News*, Nov. 2, 1893. 6 feet diameter, 120 feet high, double wall:

Exterior wall, height 20 feet, 30 feet, 30 feet, 40 feet;

“ “ thickness 21½ in., 17 in., 13 in., 8½ in.;

Interior wall, height 85 ft., 35 ft., 29 ft., 21 ft.;

“ “ thickness 13½ in., 8½ in., 4 in., 0.

Exterior diameter, 15' 6" at bottom; batter, 7/16 inch in 12 inches from bottom to 8 feet from top. Interior diameter of inside wall, 6 feet uniform to top of interior wall. Space between walls, 16 inches at bottom, diminishing to 0 at top of interior wall. The interior wall is of red brick except a lining of 4 inches of fire-brick for 20 feet from bottom.

**Stability of Chimneys.**—Chimneys must be designed to resist the maximum force of the wind in the locality in which they are built, (see Weak Chimneys, below). A general rule for diameter of base, of brick chimneys, approved by many years of practice in England and the United States, is to make the diameter of the base one tenth of the height. If the chimney is square or rectangular, make the diameter of the inscribed circle of the base one tenth of the height. The "batter" or taper of a chimney should be from 1/16 to 1/4 inch to the foot on each side. The brickwork should be one brick (8 or 9 inches) thick for the first 25 feet from the top, increasing ½ brick (4 or 4½ inches) for each 25 feet from the top downwards. If the inside diameter exceed 5 feet, the top length should be 1½ bricks; and if under 3 feet, it may be ½ brick for ten feet.

(From *The Locomotive*, 1884 and 1886.) For chimneys of four feet in diameter and one hundred feet high, and upwards, the best form is circular, with a straight batter on the outside. A circular chimney of this size, in addition to being cheaper than any other form, is lighter, stronger, and looks much better and more shapely.

Chimneys of any considerable height are not built up of uniform thickness from top to bottom, nor with a uniformly varying thickness of wall, but the wall, heaviest of course at the base, is reduced by a series of steps.

Where practicable the load on a chimney foundation should not exceed two tons per square foot in compact sand, gravel, or loam. Where a solid rock-bottom is available for foundation, the load may be greatly increased. If the rock is sloping, all unsound portions should be removed, and the face dressed to a series of horizontal steps, so that there shall be no tendency to slide after the structure is finished.

All boiler-chimneys of any considerable size should consist of an outer stack of sufficient strength to give stability to the structure, and an inner stack or core independent of the outer one. This core is by many engineers extended up to a height of but 50 or 60 feet from the base of the chimney, but the better practice is to run it up the whole height of the chimney; it may be stopped off, say, a couple feet below the top, and the outer shell contracted to the area of the core, but the better way is to run it up to about 8 or 12 inches of the top and not contract the outer shell. But under no circumstances should the core at its upper end be built into or connected with the outer stack. This has been done in several instances by bricklayers, and the result has been the expansion of the inner core which lifted the top of the outer stack squarely up and cracked the brickwork.

For a height of 100 feet we would make the outer shell in three steps, the first 20 feet high, 16 inches thick, the second 30 feet high, 12 inches thick, the

third 50 feet high and 8 inches thick. These are the minimum thicknesses admissible for chimneys of this height, and the batter should be not less than 1 in 36 to give stability. The core should also be built in three steps, each of which may be about one-third the height of the chimney, the lowest 12 inches, the middle 8 inches, and the upper step 4 inches thick. This will insure a good sound core. The top of a chimney may be protected by a cast-iron cap; or perhaps a cheaper and equally good plan is to lay the ornamental part in some good cement, and plaster the top with the same material.

**Weak Chimneys.**—James B. Francis, in a report to the Lawrence Mfg. Co. in 1873 (*Eng'g News*, Aug. 28, 1880), gives some calculations concerning the probable effects of wind on that company's chimney as then constructed. Its outer shell is octagonal. The inner shell is cylindrical, with an air-space between it and the outer shell; the two shells not being bonded together, except at the openings at the base, but with projections in the brickwork, at intervals of about 20 ft. in height, to afford lateral support by contact of the two shells. The principal dimensions of the chimney are as follows :

Height above the surface of the ground.....	211 ft.
Diameter of the inscribed circle of the octagon near the ground.....	15 "
Diameter of the inscribed circle of the octagon near the top....	10 ft. 1½ in.
Thickness of the outer shell near the base, 6 bricks, or.....	23½ in.
Thickness of the outer shell near the top, 3 bricks, or.....	11½ "
Thickness of the inner shell near the base, 4 bricks, or.....	15 "
Thickness of the inner shell near the top, 1 brick, or .....	3¾ "

One tenth of the height for the diameter of the base is the rule commonly adopted. The diameter of the inscribed circle of the base of the Lawrence Manufacturing Company's chimney being 15 ft., it is evidently much less than is usual in a chimney of that height.

Soon after the chimney was built, and before the mortar had hardened, it was found that the top had swayed over about 29 in. toward the east. This was evidently due to a strong westerly wind which occurred at that time. It was soon brought back to the perpendicular by sawing into some of the joints, and other means.

The stability of the chimney to resist the force of the wind depends mainly on the weight of its outer shell, and the width of its base. The cohesion of the mortar may add considerably to its strength; but it is too uncertain to be relied upon. The inner shell will add a little to the stability, but it may be cracked by the heat, and its beneficial effect, if any, is too uncertain to be taken into account.

The effect of the joint action of the vertical pressure due to the weight of the chimney, and the horizontal pressure due to the force of the wind is to shift the centre of pressure at the base of the chimney, from the axis toward one side, the extent of the shifting depending on the relative magnitude of the two forces. If the centre of pressure is brought too near the side of the chimney, it will crush the brickwork on that side, and the chimney will fall. A line drawn through the centre of pressure, perpendicular to the direction of the wind, must leave an area of brickwork between it and the side of the chimney, sufficient to support half the weight of the chimney; the other half of the weight being supported by the brickwork on the windward side of the line.

Different experimenters on the strength of brickwork give very different results. Kirkaldy found the weights which caused several kinds of bricks, laid in hydraulic lime mortar and in Roman and Portland cements, to fail slightly, to vary from 19 to 60 tons (of 2000 lbs.) per sq. ft. If we take in this case 25 tons per sq. ft., as the weight that would cause it to begin to fail, we shall not err greatly. To support half the weight of the outer shell of the chimney, or 322 tons, at this rate, requires an area of 12.88 sq. ft. of brickwork. From these data and the drawings of the chimney, Mr. Francis calculates that the area of 12.88 sq. ft. is contained in a portion of the chimney extending 2.428 ft. from one of its octagonal sides, and that the limit to which the centre of pressure may be shifted is therefore 5.072 ft. from the axis. If shifted beyond this, he says, on the assumption of the strength of the brickwork, it will crush and the chimney will fall.

Calculating that the wind-pressure can affect only the upper 141 ft. of the chimney, the lower 70 ft. being protected by buildings, he calculates that a wind-pressure of 44.02 lbs. per sq. ft. would blow the chimney down.

Rankine, in a paper printed in the transactions of the Institution of Engi-

neers, in Scotland, for 1867-68, says: "It had previously been ascertained by observation of the success and failure of actual chimneys, and especially of those which respectively stood and fell during the violent storms of 1856, that, in order that a round chimney may be sufficiently stable, its weight should be such that a pressure of wind, of about 55 lbs. per sq. ft. of a plane surface, directly facing the wind, or  $27\frac{1}{2}$  lbs. per sq. ft. of the plane projection of a cylindrical surface, . . . shall not cause the resultant pressure at any bed-joint to deviate from the axis of the chimney by more than one quarter of the outside diameter at that joint."

According to Rankine's rule, the Lawrence Mfg. Co.'s chimney is adapted to a maximum pressure of wind on a plane acting on the whole height of 18.80 lbs. per sq. ft., or of a pressure of 21.70 lbs. per sq. ft. acting on the uppermost 141 ft. of the chimney.

**Steel Chimneys** are largely coming into use, especially for tall chimneys of iron-works, from 150 to 300 feet in height. The advantages claimed are: greater strength and safety; smaller space required; smaller cost, by 30 to 50 per cent, as compared with brick chimneys; avoidance of infiltration of air and consequent checking of the draught, common in brick chimneys. They are usually made cylindrical in shape, with a wide curved flare for 10 to 25 feet at the bottom. A heavy cast-iron base-plate is provided, to which the chimney is riveted, and the plate is secured to a massive foundation by holding-down bolts. No guys are used. F. W. Gordon, of the Phila. Engineering Works, gives the following method of calculating their resistance to wind pressure (*Power*, Oct. 1893):

In tests by Sir William Fairbairn we find four experiments to determine the strength of thin hollow tubes. In the table will be found their elements, with their breaking strain. These tubes were placed upon hollow blocks, and the weights suspended at the centre from a block fitted to the inside of the tube.

	Clear Span, ft. in.	Thick-ness Iron, in.	Outside Diame-ter, in.	Sectional Area, in.	Breaking Weight, lbs.	Breaking W't, lbs., by Clarke's Formula, Constant 1.2.
I.	17	.037	12	1.3901	2,704	2,627
II.	15 $7\frac{1}{2}$	.113	12.4	4.3669	11,440	9,184
III.	23 5	.0631	17.68	3.487	6,400	7,302
IV.	23 5	.119	18.18	6.74	14,240	13,910

Edwin Clarke has formulated a rule from experiments conducted by him during his investigations into the use of iron and steel for hollow tube bridges, which is as follows:

$$\text{Center break. } \left. \begin{array}{l} \text{ing load, in tons.} \end{array} \right\} = \frac{\text{Area of material in sq. in.} \times \text{Mean depth in in.} \times \text{Constant}}{\text{Clear span in feet.}}$$

When the constant used is 1.2, the calculation for the tubes experimented upon by Mr. Fairbairn are given in the last column of the table. D. K. Clark's "Rules, Tables, and Data," page 513, gives a rule for hollow tubes as follows:  $W = 3.14D^2TS \div L$ .  $W$  = breaking weight in pounds in centre;  $D$  = extreme diameter in inches;  $T$  = thickness in inches;  $L$  = length between supports in inches;  $S$  = ultimate tensile strength in pounds per sq. in.

Taking  $S$ , the strength of a square inch of a riveted joint, at 35,000 lbs. per sq. in., this rule figures as follows for the different examples experimented upon by Mr. Fairbairn: I, 2870; II, 10,190; III, 7700; IV, 15,320.

This shows a close approximation to the breaking weight obtained by experiments and that derived from Edwin Clarke's and D. K. Clark's rules. We therefore assume that this system of calculation is practically correct, and that it is eminently safe when a large factor of safety is provided, and from the fact that a chimney may be standing for many years without receiving anything like the strain taken as the basis of the calculation, viz., fifty pounds per square foot. Wind pressure at fifty pounds per square foot may be assumed to be travelling in a horizontal direction, and be of the same velocity from the top to the bottom of the stack. This is the extreme assumption. If, however, the chimney is round, its effective area would be only half of its diameter plane. We assume that the entire force may be concentrated in the centre of the height of the section of the chimney under consideration.

Taking as an example a 125-foot iron chimney at Poughkeepsie, N. Y., the average diameter of which is 90 inches, the effective surface in square feet upon which the force of the wind may play will therefore be  $7\frac{1}{2}$  times 125 divided by 2, which multiplied by 50 gives a total wind force of 23,437 pounds. The resistance of the chimney to breaking across the top of the foundation would be  $3.14 \times 168^2$  (that is, diameter of base)  $\times .25 \times 35,000 \div (750 \times 4) = 258,486$ , or 10.6 times the entire force of the wind. We multiply the half height above the joint in inches, 750, by 4, because the chimney is considered a fixed beam with a load suspended on one end. In calculating its strength half way up, we have a beam of the same character. It is a fixed beam at a line half way up the chimney, where it is 90 inches in diameter and .187 inch thick. Taking the diametrical section above this line, and the force as concentrated in the centre of it, or half way up from the point under consideration, its breaking strength is:  $3.14 \times 90^2 \times .187 \times 35,000 \div (381 \times 4) = 109,220$ ; and the force of the wind to tear it apart through its cross-section,  $7\frac{1}{4} \times 62\frac{1}{2} \times 50 \div 2 = 11,352$ , or a little more than one tenth of the strength of the stack.

The Babcock & Wilcox Co.'s book "Steam" illustrates a steel chimney at the works of the Maryland Steel Co., Sparrow's Point, Md. It is 225 ft. in height above the base, with internal brick lining 13' 9" uniform inside diameter. The shell is 25 ft. diam. at the base, tapering in a curve to 17 ft. 25 ft. above the base, thence tapering almost imperceptibly to 14' 8" at the top. The upper 40 feet is of  $\frac{1}{4}$ -inch plates, the next four sections of 40 ft. each are respectively  $9\frac{3}{32}$ ,  $5\frac{1}{16}$ ,  $11\frac{3}{32}$ , and  $\frac{3}{8}$  inch.

THE STEAM-ENGINE.

**Expansion of Steam. Isothermal and Adiabatic.**—According to Mariotte's law, the volume of a perfect gas, the temperature being kept constant, varies inversely as its pressure, or  $p \propto \frac{1}{v}$ ;  $pv =$  a constant.

The curve constructed from this formula is called the *isothermal curve*, or curve of equal temperatures, and is a common or rectangular hyperbola. The relation of the pressure and volume of saturated steam, as deduced from Regnault's experiments, and as given in Steam tables, is approximately, according to Rankine (S. E., p. 403), for pressures not exceeding 120 lbs.,  $p \propto \frac{1}{v^{1\frac{1}{6}}}$ , or  $p \propto v^{-\frac{17}{16}}$ , or  $pv^{1\frac{1}{6}} = pv^{1.0625} =$  a constant. Zeuner has found that the exponent 1.0646 gives a closer approximation.

When steam expands in a closed cylinder, as in an engine, according to Rankine (S. E., p. 385), the approximate law of the expansion is  $p \propto \frac{1}{v^{1\frac{1}{9}}}$ , or  $p \propto v^{-\frac{10}{9}}$ , or  $pv^{1.111} =$  a constant. The curve constructed from this formula is called the *adiabatic curve*, or curve of no transmission of heat.

Peabody (Therm., p. 112) says: "It is probable that this equation was obtained by comparing the expansion lines on a large number of indicator-diagrams. . . . There does not appear to be any good reason for using an exponential equation in this connection, . . . and the action of a lagged steam-engine cylinder is far from being adiabatic. . . . For general purposes the hyperbola is the best curve for comparison with the expansion curve of an indicator-card. . . ." Wolff and Denton, Trans. A. S. M. E., ii. 175, say: "From a number of cards examined from a variety of steam-engines in current use, we find that the actual expansion line varies between the 10/9 adiabatic curve and the Mariotte curve."

Prof. Thurston (A. S. M. E., ii. 203), says he doubts if the exponent ever becomes the same in any two engines, or even in the same engines at different times of the day and under varying conditions of the day.

**Expansion of Steam according to Mariotte's Law and to the Adiabatic Law.** (Trans. A. S. M. E., ii. 156.)—Mariotte's law

$pv = p_1v_1$ ; values calculated from formula  $\frac{P_m}{p_1} = \frac{1}{R}(1 + \text{hyp log } R)$ , in which  $R = v_2 \div v_1$ ,  $p_1 =$  absolute initial pressure,  $P_m =$  absolute mean pressure,  $v_1 =$  initial volume of steam in cylinder at pressure  $p_1$ ,  $v_2 =$  final volume of steam at final pressure. Adiabatic law:  $pv^{\frac{10}{9}} = p_1v_1^{\frac{10}{9}}$ ; values calculated from formula  $\frac{P_m}{p_1} = 10R^{-1} - 9R^{-\frac{10}{9}}$ .

**Mean Pressure of Expanded Steam.**—For calculations of engines it is generally assumed that steam expands according to Mariotte's law, the curve of the expansion line being a hyperbola. The mean pressure, measured above vacuum, is then obtained from the formula

$$P_m = p_1 \frac{1 + \text{hyp log } R}{R}, \text{ or } P_m = P_t(1 + \text{hyp log } R),$$

in which  $P_m$  is the absolute mean pressure,  $p_1$  the absolute initial pressure taken as uniform up to the point of cut-off,  $P_t$  the terminal pressure, and  $R$  the ratio of expansion. If  $l$  = length of stroke to the cut-off,  $L$  = total stroke.

$$P_m = \frac{p_1 l + p_1 l \text{ hyp log } \frac{L}{l}}{L}; \text{ and if } R = \frac{L}{l}, P_m = p_1 \frac{1 + \text{hyp log } R}{R}.$$

**Mean and Terminal Absolute Pressures.—Mariotte's Law.**—The values in the following table are based on Mariotte's law, except those in the last column, which give the mean pressure of superheated steam, which, according to Rankine, expands in a cylinder according to the law  $p \propto v^{-\frac{1}{8}}$ . These latter values are calculated from the formula  $\frac{P_m}{p_1} = \frac{17 - 16R^{-\frac{1}{8}}}{R}$ .  $R^{-\frac{1}{8}}$  may be found by extracting the square root of  $\frac{1}{R}$  four times. From the mean absolute pressures given deduct the mean back pressure (absolute) to obtain the mean effective pressure.

Rate of Expansion.	Cut-off.	Ratio of Mean to Initial Pressure.	Ratio of Mean to Terminal Pressure.	Ratio of Terminal to Mean Pressure.	Ratio of Initial to Mean Pressure.	Ratio of Mean to Initial Dry Steam.

**Calculation of Mean Effective Pressure, Clearance and Compression Considered.**—In the above tables no account is taken

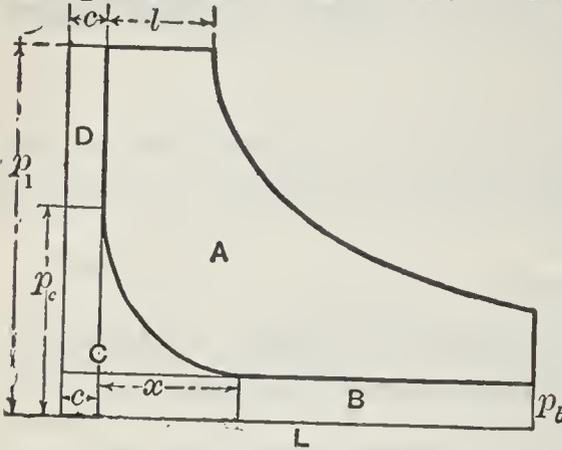

FIG. 137.

of clearance, which in actual steam-engines modifies the ratio of expansion and the mean pressure; nor of compression and back-pressure, which diminish the mean effective pressure. In the following calculation these elements are considered.

$L$  = length of stroke,  $l$  = length before cut-off,  $x$  = length of compression part of stroke,  $c$  = clearance,  $p_1$  = initial pressure,  $p_b$  = back pressure,  $p_c$  = pressure of clearance steam at end of compression. All pressures are absolute, that is, measured from a perfect vacuum.

$$\text{Area of ABCD} = p_1(l + c) \left( 1 + \text{hyp log } \frac{L + c}{l + c} \right);$$

$$B = p_b(L - x);$$

$$C = p_c c \left( 1 + \text{hyp log } \frac{x + c}{c} \right) = p_b(x + c) \left( 1 + \text{hyp log } \frac{x + c}{c} \right);$$

$$D = (p_1 - p_c)c = p_1c - p_b(x + c).$$

$$\text{Area of A} = \text{ABCD} - (B + C + D)$$

$$= p_1(l + c) \left( 1 + \text{hyp log } \frac{L + c}{l + c} \right)$$

$$- \left[ p_b(L - x) + p_b(x + c) \left( 1 + \text{hyp log } \frac{x + c}{c} \right) + p_1c - p_b(x + c) \right]$$

$$= p_1(l + c) \left( 1 + \text{hyp log } \frac{L + c}{l + c} \right)$$

$$- p_b \left[ (L - x) + (x + c) \text{hyp log } \frac{x + c}{c} \right] - p_1c.$$

$$\text{Mean effective pressure} = \frac{\text{area of A}}{L}.$$

EXAMPLE.—Let  $L = 1$ ,  $l = 0.25$ ,  $x = 0.25$ ,  $c = 0.1$ ,  $p_1 = 60$  lbs.,  $p_b = 2$  lbs.

$$\text{Area A} = 60(.25 + .1) \left( 1 + \text{hyp log } \frac{1.1}{.35} \right)$$

$$- 2 \left[ (1 - .25) + .35 \text{hyp log } \frac{.35}{.1} \right] - 60 \times .1$$

$$= 21(1 + 1.145) - 2[.75 + .35 \times 1.253] - 6$$

$$= 45.045 - 2.377 - 6 = 36.668 = \text{mean effective pressure.}$$

The actual indicator-diagram generally shows a mean pressure considerably less than that due to the initial pressure and the rate of expansion. The causes of loss of pressure are: 1. Friction in the stop-valves and steam-pipes. 2. Friction or wire-drawing of the steam during admission and cut-off, due chiefly to defective valve-gear and contracted steam-passages. 3. Liquefaction during expansion. 4. Exhausting before the engine has completed its stroke. 5. Compression due to early closure of exhaust. 6. Friction in the exhaust-ports, passages, and pipes.

Re-evaporation during expansion of the steam condensed during admission, and valve-leakage after cut-off, tend to elevate the expansion line of the diagram and increase the mean pressure.

If the theoretical mean pressure be calculated from the initial pressure and the rate of expansion on the supposition that the expansion curve fol-

lows Mariotte's law,  $pv = a$  constant, and the necessary corrections are made for clearance and compression, the expected mean pressure in practice may be found by multiplying the calculated results by the factor in the following table, according to Seaton.

Particulars of Engine.	Factor.
Expansive engine, special valve-gear, or with a separate cut-off valve, cylinder jacketed . . . . .	0.94
Expansive engine having large ports, etc., and good ordinary valves, cylinders jacketed . . . . .	0.9 to 0.92
Expansive engines with the ordinary valves and gear as in general practice, and unjacketed . . . . .	0.8 to 0.85
Compound engines, with expansion valve to h.p. cylinder; cylinders jacketed, and with large ports, etc. . . . .	0.9 to 0.92
Compound engines, with ordinary slide-valves, cylinders jacketed, and good ports, etc. . . . .	0.8 to 0.85
Compound engines as in general practice in the merchant service, with early cut-off in both cylinders, without jackets and expansion-valves . . . . .	0.7 to 0.8
Fast-running engines of the type and design usually fitted in war-ships . . . . .	0.6 to 0.8

If no correction be made for clearance and compression, and the engine is in accordance with general modern practice, the theoretical mean pressure may be multiplied by 0.96, and the product by the proper factor in the table, to obtain the expected mean pressure.

**Given the Initial Pressure and the Average Pressure, to Find the Ratio of Expansion and the Period of Admission.**

- $P$  = initial absolute pressure in lbs. per sq. in.;
- $p$  = average total pressure during stroke in lbs. per sq. in.;
- $L$  = length of stroke in inches;
- $l$  = period of admission measured from beginning of stroke;
- $c$  = clearance in inches;

$$R = \text{actual ratio of expansion} = \frac{L+c}{l+c} \dots \dots \dots (1)$$

$$p = \frac{P(1 + \text{hyp log } R)}{R}$$

To find average pressure  $p$ , taking account of clearance,

$$p = \frac{P(l+c) + P(l+c) \text{ hyp log } R - Pc}{L} \dots \dots \dots (2)$$

whence

$$pL + Pc = P(l+c)(1 + \text{hyp log } R);$$

$$\text{hyp log } R = \frac{pL + Pc}{Pl + Pc} - 1 = \frac{\frac{p}{P}L + c}{l+c} - 1 \dots \dots \dots (3)$$

Given  $p$  and  $P$ , to find  $R$  and  $l$  (by trial and error).—There being two unknown quantities  $R$  and  $l$ , assume one of them, viz., the period of admission  $l$ , substitute it in equation (3) and solve for  $R$ . Substitute this value of  $R$  in the formula (1), or  $l = \frac{L+c}{R} - c$ , obtained from formula (1), and find  $l$ . If the result is greater than the assumed value of  $l$ , then the assumed value of the period of admission is too long; if less, the assumed value is too short. Assume a new value of  $l$ , substitute it in formula (3) as before, and continue by this method of trial and error till the required values of  $R$  and  $l$  are obtained.

EXAMPLE.— $P = 70$ ,  $p = 42.78$ ,  $L = 60''$ ,  $c = 3''$ , to find  $l$ . Assume  $l = 21$  in.

$$\text{hyp log } R = \frac{\frac{p}{P}L + c}{l+c} - 1 = \frac{\frac{42.78}{70} \times 60 + 3}{21 + 3} - 1 = 1.653 - 1 = .653;$$

$$\text{hyp log } R = .653, \text{ whence } R = 1.92.$$

$$l = \frac{L + c}{R} - c = \frac{63}{192} - 3 = 29.8,$$

which is greater than the assumed value, 21 inches.

Now assume  $l = 15$  inches :

$$\text{hyp log } R = \frac{\frac{42.78}{70} \times 60 + 3}{15 + 3} - 1 = 1.204, \text{ whence } R = 3.5;$$

$$l = \frac{L + c}{R} - c = \frac{63}{3.5} - 3 = 18 - 3 = 15 \text{ inches, the value assumed.}$$

Therefore  $R = 3.5$ , and  $l = 15$  inches.

*Period of Admission Required for a Given Actual Ratio of Expansion:*

$$l = \frac{L + c}{R} - c, \text{ in inches . . . . . (4)}$$

$$\text{In percentage of stroke, } l = \frac{100 + \text{p.ct. clearance}}{R} - \text{p. ct. clearance. . . (5)}$$

$$\text{Terminal pressure} = \frac{P(l + c)}{L + c} = \frac{P}{R}. \text{ . . . . . (6)}$$

*Pressure at any other Point of the Expansion.*—Let  $L_1$  = length of stroke up to the given point.

$$\text{Pressure at the given point} = \frac{P(l + c)}{L_1 + c}. \text{ . . . . . (7)}$$

**WORK OF STEAM IN A SINGLE CYLINDER.**

To facilitate calculations of steam expanded in cylinders the table on the next page is abridged from Clark on the Steam-engine. The actual ratios of expansion, column 1, range from 1.0 to 8.0, for which the hyperbolic logarithms are given in column 2. The 3d column contains the periods of admission relative to the actual ratios of expansion, as percentages of the stroke, calculated by formula (5) above. The 4th column gives the values of the mean pressures relative to the initial pressures, the latter being taken as 1, calculated by formula (2). In the calculation of columns 3 and 4, clearance is taken into account, and its amount is assumed at 7% of the stroke. The final pressures, in the 5th column, are such as would be arrived at by the continued expansion of the whole of the steam to the end of the stroke, the initial pressure being equal to 1. They are the reciprocals of the ratios of expansion, column 1. The 6th column contains the relative total performances of equal weights of steam worked with the several actual ratios of expansion; the total performance, when steam is admitted for the whole of the stroke, without expansion, being equal to 1. They are obtained by dividing the figures in column 4 by those in column 5.

The pressures have been calculated on the supposition that the pressure of steam, during its admission into the cylinder, is uniform up to the point of cutting off, and that the expansion is continued regularly to the end of the stroke. The relative performances have been calculated without any allowance for the effect of compressive action.

The calculations have been made for periods of admission ranging from 100%, or the whole of the stroke, to 6.4%, or 1/16 of the stroke. And though, nominally, the expansion is 16 times in the last instance, it is actually only 8 times, as given in the first column. The great difference between the nominal and the actual ratios of expansion is caused by the clearance, which is equal to 7% of the stroke, and causes the nominal volume of steam admitted, namely, 6.4%, to be augmented to 6.4 + 7 = 13.4% of the stroke, or, say, double, for expansion. When the steam is cut off at 1/9, the actual expansion is only 6 times; when cut off at 1/5, the expansion is 4 times; when cut off at 1/3, the expansion is 2 2/3 times; and to effect an actual expansion to twice the initial volume, the steam is cut off at 46 1/2% of the stroke, not at half-stroke.

**Expansive Working of Steam—Actual Ratios of Expansion, with the Relative Periods of Admission, Pressures, and Performance.**

Steam-pressure 100 lbs. absolute. Clearance at each end of the cylinder 7% of the stroke.

ASSUMPTIONS OF THE TABLE.—That the initial pressure is uniform; that the expansion is complete to the end of the stroke; that the pressure in expansion varies inversely as the volume; that there is no back-pressure of exhaust or of compression, and that clearance is 7% of the stroke at each end of the cylinder. No allowance has been made for loss of steam by cylinder-condensation or leakage.

Volume of 1 lb. of steam of 100 lbs. pressure per sq. in., or 14,400 lbs. per sq. ft. .... 4.33 cu. ft.  
 Product of initial pressure and volume ..... 62,352 ft.-lbs.

Though a uniform clearance of 7% at each end of the stroke has been assumed as an average proportion for the purpose of compiling the table, the clearance of cylinders with ordinary slides varies considerably—say from 5% to 10%. (With Corliss engines it is sometimes as low as 2%.) With the clearance, 7%, that has been assumed, the table gives approximate results sufficient for most practical purposes, and more trustworthy than results deduced by calculations based on simple tables of hyperbolic logarithms, where clearance is neglected.

Weight of steam of 100 lbs. total initial pressure admitted for one stroke, per cubic foot of net capacity of the cylinder, in decimals of a pound = reciprocal of figures in column 9.

Total actual work done by steam of 100 lbs. total initial pressure in one stroke per cubic foot of net capacity of cylinder, in foot-pounds = figures in column 7 ÷ figures in column 9.

**RULE 1:** To find the net capacity of cylinder for a given weight of steam admitted for one stroke, and a given actual ratio of expansion. (Column 9 of table.)—Multiply the volume of 1 lb. of steam of the given pressure by the given weight in pounds, and by the actual ratio of expansion. Multiply the product by 100, and divide by 100 plus the percentage of clearance. The quotient is the net capacity of the cylinder.

**RULE 2:** To find the net capacity of cylinder for the performance of a given amount of total actual work in one stroke, with a given initial pressure and actual ratio of expansion.—Divide the given work by the total actual work done by 1 lb. of steam of the same pressure, and with the same actual ratio of expansion; the quotient is the weight of steam necessary to do the given work, for which the net capacity is found by Rule 1 preceding.

**NOTE.**—1. Conversely, the weight of steam admitted per cubic foot of net capacity for one stroke is the reciprocal of the cylinder-capacity per pound of steam, as obtained by Rule 1.

2. The total actual work done per cubic foot of net capacity for one stroke is the reciprocal of the cylinder-capacity per foot-pound of work done, as obtained by Rule 2.

3. The total actual work done per square inch of piston per foot of the stroke is 1/144th part of the work done per cubic foot.

4. The resistance of back pressure of exhaust and of compression are to be added to the net work required to be done, to find the total actual work.

**APPENDIX TO ABOVE TABLE—MULTIPLIERS FOR NET CYLINDER-CAPACITY, AND TOTAL ACTUAL WORK DONE.**

(For steam of other pressures than 100 lbs. per square inch.)

Total Pressures per square inch.	Multipliers.		Total Pressures per square inch.	Multipliers.	
	For Col. 7. Total Work by 1 lb. of Steam.	For Col. 9. Capacity of Cylinder.		For Col. 7. Total Work by 1 lb. of Steam.	For Col. 9. Capacity of Cylinder.
lbs.			lbs.		
65	.975	1.50	100	1.000	1.00
70	.981	1.40	110	1.009	.917
75	.986	1.31	120	1.011	.843
80	.988	1.24	130	1.015	.781
85	.991	1.17	140	1.022	.730
90	.995	1.11	150	1.025	.683
95	.998	1.05	160	1.031	.644

The figures in the second column of this table are derived by multiplying the total pressure per square foot of any given steam by the volume in cubic feet of 1 lb. of such steam, and dividing the product by 62,352, which is the product in foot-pounds for steam of 100 lbs. pressure. The quotient is the multiplier for the given pressure.

The figures in the third column are the quotients of the figures in the second column divided by the ratio of the pressure of the given steam to 100 lbs.

**Measures for Comparing the Duty of Engines.**—Capacity is measured in horse-powers, expressed by the initials, H.P.: 1 H.P. = 33,000 ft.-lbs. per minute, = 550 ft.-lbs. per second, = 1,980,000 ft.-lbs. per hour

1 ft.-lb. = a pressure of 1 lb. exerted through a space of 1 ft. Economy is measured, 1, in pounds of coal per horse-power per hour; 2, in pounds of steam per horse-power per hour. The second of these measures is the more accurate and scientific, since the engine uses steam and not coal, and it is independent of the economy of the boiler.

In gas-engine tests the common measure is the number of cubic feet of gas (measured at atmospheric pressure) per horse-power, but as all gas is not of the same quality, it is necessary for comparison of tests to give the analysis of the gas. When the gas for one engine is made in one gas-producer, then the number of pounds of coal used in the producer per hour per horse-power of the engine is the proper measure of economy.

Economy, or duty of an engine, is also measured in the number of foot-pounds of work done per pound of fuel. As 1 horse-power is equal to 1,980,000 ft.-lbs. of work in an hour, a duty of 1 lb. of coal per H.P. per hour would be equal to 1,980,000 ft.-lbs. per lb. of fuel; 2 lbs. per H.P. per hour equals 990,000 ft.-lbs. per lb. of fuel, etc.

The duty of pumping-engines is commonly expressed by the number of foot-pounds of work done per 100 lbs. of coal.

When the duty of a pumping-engine is thus given, the equivalent number of pounds of fuel consumed per horse-power per hour is found by dividing 198 by the number of millions of foot-pounds of duty. Thus a pumping-engine giving a duty of 99 millions is equivalent to  $198/99 = 2$  lbs. of fuel per horse-power per hour.

**Efficiency Measured in Thermal Units per Minute.**—Some writers express the efficiency of an engine in terms of the number of thermal units used by the engine per minute for each indicated horse-power, instead of by the number of pounds of steam used per hour.

The heat chargeable to an engine per pound of steam is the difference between the total heat in a pound of steam at the boiler-pressure and that in a pound of the feed-water entering the boiler. In the case of condensing engines, suppose we have a temperature in the hot-well of 101° F., corresponding to a vacuum of 28 in. of mercury, or an absolute pressure of 1 lb. per sq. in. above a perfect vacuum: we may feed the water into the boiler at that temperature. In the case of a non-condensing-engine, by using a portion of the exhaust steam in a good feed-water heater, at a pressure a trifle above the atmosphere (due to the resistance of the exhaust passages through the heater), we may obtain feed-water at 212°. One pound of steam used by the engine then would be equivalent to thermal units as follows:

Pressure of steam by gauge:	50	75	100	125	150	175	200
Total heat in steam above 32°:	1172.8	1179.6	1185.0	1189.5	1193.5	1197.0	1200.2

Subtracting 69.1 and 180.9 heat-units, respectively, the heat above 32° in feed-water of 101° and 212° F., we have—

Heat given by boiler:							
Feed at 101°.....	1103.7	1110.5	1115.9	1120.4	1124.4	1127.9	1131.1
Feed at 212°.....	991.9	998.7	1004.1	1008.6	1012.6	1016.1	1019.3

Thermal units per minute used by an engine for each pound of steam used per indicated horse-power per hour:

Feed at 101°.....	18.40	18.51	18.60	18.67	18.74	18.80	18.85
Feed at 212°.....	16.53	16.65	16.74	16.81	16.88	16.94	16.99

**EXAMPLES.**—A triple-expansion engine, condensing, with steam at 175 lbs., gauge and vacuum 28 in., uses 13 lbs. of water per I.H.P. per hour, and a high-speed non-condensing engine, with steam at 100 lbs. gauge, uses 30 lbs. How many thermal units per minute does each consume?

*Ans.*— $13 \times 18.80 = 244.4$ , and  $30 \times 16.74 = 502.2$  thermal units per minute.

A perfect engine converting all the heat-energy of the steam into work would require  $33,000 \text{ ft.-lbs.} \div 778 = 42.4164$  thermal units per minute per indicated horse-power. This figure, 42.4164, therefore, divided by the number of thermal units per minute per I.H.P. consumed by an engine, gives its efficiency as compared with an ideally perfect engine. In the examples above, 42.4164 divided by 244.4 and by 502.2 gives 17.35% and 8.45% efficiency, respectively.

**Total Work Done by One Pound of Steam Expanded in a Single Cylinder.** (Column 7 of table.)—If 1 pound of water be converted into steam of atmospheric pressure = 2116.8 lbs. per sq. ft., it occupies a volume equal to 26.36 cu. ft. The work done is equal to 2116.8 lbs.

**Relative Efficiency of 1 lb. of Steam with and without Clearance;** back pressure and compression not considered.

$$\text{Mean total pressure} = p = \frac{P(l+c) + P(l+c) \text{ hyp. log. } R - Pc}{L}$$

Let  $P = 1$ ;  $L = 100$ ;  $l = 25$ ;  $c = 7$ .

$$p = \frac{32 + 32 \text{ hyp. log. } \frac{107}{32} - 7}{100} = \frac{32 + 32 \times 1.209 - 7}{100} = .637.$$

If the clearance be added to the stroke, so that clearance becomes zero, the same quantity of steam being used, admission  $l$  being then  $= l + c = 32$ , and stroke  $L + c = 107$ .

$$p_1 = \frac{32 + 32 \text{ hyp. log. } \frac{107}{32} - 0}{107} = \frac{32 + 32 \times 1.209}{107} = .707.$$

That is, if the clearance be reduced to 0, the amount of the clearance 7 being added to both the admission and the stroke, the same quantity of steam will do more work than when the clearance is 7 in the ratio 707 : 637, or 11% more.

**Back Pressure Considered.**—If back pressure = .10 of  $P$ , this amount has to be subtracted from  $p$  and  $p_1$ , giving  $p = .537$ ,  $p_1 = .607$ , the work of a given quantity of steam used without clearance being greater than when clearance is 7 per cent in the ratio of 607 : 537, or 13% more.

**Effect of Compression.**—By early closure of the exhaust, so that a portion of the exhaust-steam is compressed into the clearance-space, much of the loss due to clearance may be avoided. If expansion is continued down to the back pressure, if the back pressure is uniform throughout the exhaust-stroke, and if compression begins at such point that the exhaust-steam remaining in the cylinder is compressed to the initial pressure at the end of the back stroke, then the work of compression of the exhaust-steam equals the work done during expansion by the clearance-steam. The clearance-space being filled by the exhaust-steam thus compressed, no new steam is required to fill the clearance-space for the next forward stroke, and the work and efficiency of the steam used in the cylinder are just the same as if there were no clearance and no compression. When, however, there is a drop in pressure from the final pressure of the expansion, or the terminal pressure, to the exhaust or back pressure (the usual case), the work of compression to the initial pressure is greater than the work done by the expansion of the clearance-steam, so that a loss of efficiency results. In this case a greater efficiency can be attained by inclosing for compression a less quantity of steam than that needed to fill the clearance-space with steam of the initial pressure. (See Clark, S. E., p. 399, *et seq.*; also F. H. Ball, Trans. A. S. M. E., xiv. 1067.) It is shown by Clark that a somewhat greater efficiency is thus attained whether or not the pressure of the steam be carried down by expansion to the back exhaust-pressure. As a result of calculations to determine the most efficient periods of compression for various percentages of back pressure, and for various periods of admission, he gives the table on the next page :

**Clearance in Low- and High-speed Engines.** (Harris Tabor, *Am. Mach.*, Sept. 17, 1891.)—The construction of the high-speed engine is such, with its relatively short stroke, that the clearance must be much larger than in the releasing-valve type. The short-stroke engine is, of necessity, an engine with large clearance, which is aggravated when a variable compression is a feature. Conversely, the releasing-valve gear is, from necessity, an engine of slow rotative speed, where great power is obtainable from long stroke, and small clearance is a feature in its construction. In one case the clearance will vary from 8% to 12% of the piston-displacement, and in the other from 2% to 3%. In the case of an engine with a clearance equalling 10% of the piston-displacement the waste room becomes enormous when considered in connection with an early cut-off. The system of compounding reduces the waste due to clearance in proportion as the steam is expanded to a lower pressure. The farther expansion is carried through a train of cylinders the greater will be the reduction of waste due to clearance. This is shown from the fact that the high-speed engine, expanding

steam much less than the Corliss, will show a greater gain when changed from simple to compound than its rival under similar conditions.

COMPRESSION OF STEAM IN THE CYLINDER.

Best Periods of Compression; Clearance 7 per cent.

Cut-off in Percentages of the Stroke.	Total Back Pressure, in percentages of the total initial pressure.							
	2½	5	10	15	20	25	30	35
	Periods of Compression, in parts of the stroke.

70	19	17	16	14	14	12	10	8
75	17	16	14	13	12	11	9	8

NOTES TO TABLE.—1. For periods of admission, or percentages of back pressure, other than those given, the periods of compression may be readily found by interpolation.

2. For any other clearance, the values of the tabulated periods of compression are to be altered in the ratio of 7 to the given percentage of clearance.

Cylinder-condensation may have considerable effect upon the best point of compression, but it has not yet (1893) been determined by experiment. (Trans. A. S. M. E., xiv. 1078.)

**Cylinder-condensation.**—Rankine, S. E., p. 421, says: Conduction of heat to and from the metal of the cylinder, or to and from liquid water contained in the cylinder, has the effect of lowering the pressure at the beginning and raising it at the end of the stroke, the lowering effect being on the whole greater than the raising effect. In some experiments the quantity of steam wasted through alternate liquefaction and evaporation in the cylinder has been found to be greater than the quantity which performed the work.

**Percentage of Loss by Cylinder-condensation, taken at Cut-off.** (From circular of the Ashcroft Mfg. Co. on the Tabor Indicator, 1889.)

Percentage of Stroke completed at Cut-off.	Percent. of Feed-water accounted for by the Indicator diagram.			Percent. of Feed-water Consumption due to Cylinder-condensation.		
	Simple Engines.	Compound Engines, h.p. cyl.	Triple-expansion Engines, h.p. cyl.	Simple Engines.	Compound Engines, h.p. cyl.	Triple-expansion Engines, h.p. cyl.
5	58	.....	.....	42	.....	.....
10	66	74	.....	34	26	.....
15	71	76	78	29	24	22
20	74	78	80	26	22	20
30	78	82	84	22	18	16
40	82	85	87	18	15	13
50	86	88	90	14	12	10

**Theoretical Compared with Actual Water-consumption, Single-cylinder Automatic Cut-off Engines.** (From the catalogue of the Buckeye Engine Co.)—The following table has been prepared on the basis of the pressures that result in practice with a constant boiler-pressure of 80 lbs. and different points of cut-off, with Buckeye engines and others with similar clearance. Fractions are omitted, except in the percentage column, as the degree of accuracy their use would seem to imply is not attained or aimed at.

Cut-off Part of Stroke.	Mean Effective Pressure.	Total Terminal Pressure.	Indicated Rate, lbs. Water, per I.H.P. per hour.	Assumed.	
				Act'l Rate.	Per ct. Loss.
.10	18	11	20	32	58
.15	27	15	19	27	41
.20	35	20	19	25	31.5
.25	42	25	20	25	25
.30	48	30	20	24	21.8
.35	53	35	21	25	19
.40	57	38	22	26	16.7
.45	61	43	23	27	15
.50	64	48	24	27	13.6

It will be seen that while the best indicated economy is when the cut-off is about at .15 or .20 of the stroke, giving about 30 lbs. M.E.P., and a terminal 3 or 4 lbs. above atmosphere, when we come to add the percentages due to a constant amount of unindicated loss, as per sixth column, the most economical point of cut-off is found to be about .30 of the stroke, giving 48 lbs. M.E.P. and 30 lbs. terminal pressure. This showing agrees substantially with modern experience under automatic cut-off regulation.

**Experiments on Cylinder-condensation.**—Experiments by Major Thos. English (*Eng'g*, Oct. 7, 1887, p. 386) with an engine 10 × 14 in., jacketed in the sides but not on the ends, indicate that the net initial condensation (or excess of condensation over re-evaporation) by the clearance surface varies directly as the initial density of the steam, and inversely as the square root of the number of revolutions per unit of time. The mean results gave for the net initial condensation by clearance-space per sq. ft. of surface at one rev. per second 6.06 thermal units in the engine when run non-condensing and 5.75 units when condensing.

G. R. Bodmer (*Eng'g*, March 4, 1892, p. 299) says: Within the ordinary limits of expansion desirable in one cylinder the expansion ratio has practically no influence on the amount of condensation per stroke, which for simple engines can be expressed by the following formula for the weight of water condensed [per minute, probably; the original does not state]:

$$W = C \frac{S(T-t)}{L \sqrt[3]{N^2}}$$
 where  $T$  denotes the mean admission temperature,  $t$  the mean exhaust temperature,  $S$  clearance-surface (square feet),  $N$  the number of revolutions per second,  $L$  latent heat of steam at the mean admission temperature, and  $C$  a constant for any given type of engine.

Mr. Bodmer found from experimental data that for high-pressure non-jacketed engines  $C$  = about 0.11, for condensing non-jacketed engines 0.085 to 0.11, for condensing jacketed engines 0.085 to 0.053. The figures for jacketed engines apply to those jacketed in the usual way, and not at the ends.

$C$  varies for different engines of the same class, but is practically constant for any given engine. For simple high-pressure non-jacketed engines it was found to range from 0.1 to 0.112.

Applying Mr. Bodmer's formula to the case of a Corliss non-jacketed non-condensing engine, 4-ft. stroke, 24 in. diam, 60 revs. per min., initial pressure 90 lbs. gauge, exhaust pressure 2 lbs., we have  $T - t = 112^\circ$ ,  $N = 1$ ,  $L = 880$ ,  $S = 7$  sq. ft.; and, taking  $C = .112$  and  $W =$  lbs. water condensed per minute,  $W = \frac{.112 \times 112 \times 7}{1 \times 880} = .09$  lb. per minute, or 5.4 lbs. per hour. If the steam used per I.H.P. per hour according to the diagram is 20 lbs., the actual water consumption is 25.4 lbs., corresponding to a cylinder condensation of 27%.

## INDICATOR-DIAGRAM OF A SINGLE-CYLINDER ENGINE.

**Definitions.**—*The Atmospheric Line, AB,* is a line drawn by the pencil of the indicator when the connections with the engine are closed and both sides of the piston are open to the atmosphere.

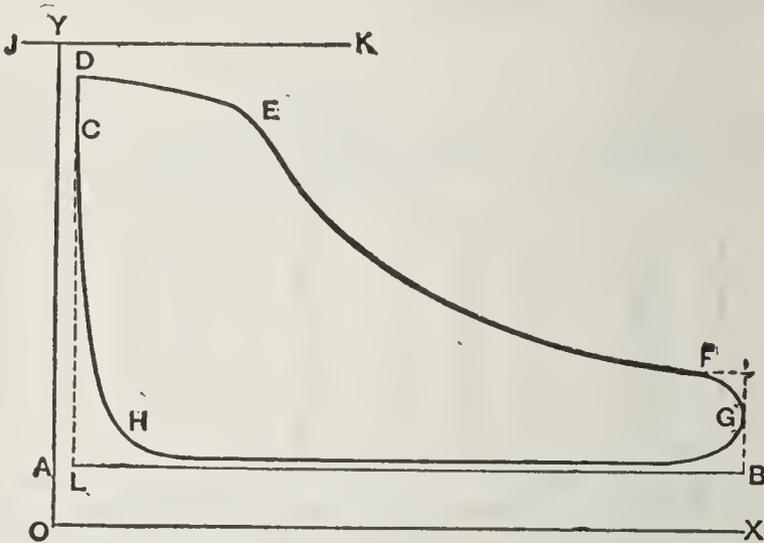

FIG. 138.

*The Vacuum Line, OX,* is a reference line usually drawn about  $14 \frac{7}{10}$  pounds by scale below the atmospheric line.

*The Clearance Line, OY,* is a reference line drawn at a distance from the end of the diagram equal to the same per cent of its length as the clearance and waste room is of the piston-displacement.

*The Line of Boiler-pressure, JK,* is drawn parallel to the atmospheric line, and at a distance from it by scale equal to the boiler-pressure shown by the gauge.

*The Admission Line, CD,* shows the rise of pressure due to the admission of steam to the cylinder by opening the steam-valve.

*The Steam Line, DE,* is drawn when the steam-valve is open and steam is being admitted to the cylinder.

*The Point of Cut-off, E,* is the point where the admission of steam is stopped by the closing of the valve. It is often difficult to determine the exact point at which the cut-off takes place. It is usually located where the outline of the diagram changes its curvature from convex to concave.

*The Expansion Curve, EF,* shows the fall in pressure as the steam in the cylinder expands doing work.

*The Point of Release, F,* shows when the exhaust-valve opens.

*The Exhaust Line, FG,* represents the change in pressure that takes place when the exhaust-valve opens.

*The Back-pressure Line, GH,* shows the pressure against which the piston acts during its return stroke.

*The Point of Exhaust Closure, H,* is the point where the exhaust-valve closes. It cannot be located definitely, as the change in pressure is at first due to the gradual closing of the valve.

*The Compression Curve, HC,* shows the rise in pressure due to the compression of the steam remaining in the cylinder after the exhaust-valve has closed.

*The Mean Height of the Diagram* equals its area divided by its length.

*The Mean Effective Pressure* is the mean net pressure urging the piston forward = the mean height  $\times$  the scale of the indicator-spring.

*To find the Mean Effective Pressure from the Diagram.*—Divide the length,  $LB,$  into a number, say 10, equal parts, setting off half a part at  $L,$  half a part at  $B,$  and nine other parts between; erect ordinates perpendicular to the atmospheric line at the points of division of  $LB,$  cutting the diagram; add together the lengths of these ordinates intercepted between the upper and lower lines of the diagram and divide by their number. This

gives the mean height, which multiplied by the scale of the indicator-spring gives the M.E.P. Or find the area by a planimeter, or other means (see Mensuration, p. 55), and divide by the length  $LB$  to obtain the mean height.

The *Initial Pressure* is the pressure acting on the piston at the beginning of the stroke.

The *Terminal Pressure* is the pressure above the line of perfect vacuum that would exist at the end of the stroke if the steam had not been released earlier. It is found by continuing the expansion-curve to the end of the diagram.

### INDICATED HORSE-POWER OF ENGINES, SINGLE-CYLINDER.

$$\text{Indicated Horse-power I.H.P.} = \frac{PLan}{33,000}$$

In which  $P$  = mean effective pressure in lbs. per sq. in.;  $L$  = length of stroke in feet;  $a$  = area of piston in square inches. For accuracy, one half of the sectional area of the piston-rod must be subtracted from the area of the piston if the rod passes through one head, or the whole area of the rod if it passes through both heads;  $n$  = No. of single strokes per min. =  $2 \times$  No. of revolutions.

$$\text{I.H.P.} = \frac{PaS}{33,000}, \text{ in which } S = \text{piston speed in feet per minute.}$$

$$\text{I.H.P.} = \frac{FLd^2n}{42,017} = \frac{Pd^2S}{42,017} = .0000238PLd^2n = .0000238Pd^2S,$$

In which  $d$  = diam. of cyl. in inches. (The figures 238 are exact, since  $7854 \div 33 = 23.8$  exactly.) If product of piston-speed  $\times$  mean effective pressure = 42,017, then the horse-power would equal the square of the diameter in inches.

**Handy Rule for Estimating the Horse-power of a Single-cylinder Engine.**—Square the diameter and divide by 2. This is correct whenever the product of the mean effective pressure and the piston-speed =  $\frac{1}{2}$  of 42,017, or, say, 21,000, viz., when M.E.P. = 30 and  $S = 700$ ; when M.E.P. = 35 and  $S = 600$ ; when M.E.P. = 38.2 and  $S = 550$ ; and when M.E.P. = 42 and  $S = 500$ . These conditions correspond to those of ordinary practice with both Corliss engines and shaft-governor high-speed engines.

**Given Horse-power, Mean Effective Pressure, and Piston-speed, to find Size of Cylinder.**—

$$\text{Area} = \frac{33,000 \times \text{I.H.P.}}{PLn} \quad \text{Diameter} = 205 \sqrt{\frac{\text{I.H.P.}}{PS}}. \text{ (Exact.)}$$

**Brake Horse-power** is the actual horse-power of the engine as measured at the fly-wheel by a friction-brake or dynamometer. It is the indicated horse-power minus the friction of the engine.

**Table for Roughly Approximating the Horse-power of a Compound Engine from the Diameter of its Low-pressure Cylinder.**—The indicated horse-power of an engine being

$\frac{Psd^2}{42,017}$ , in which  $P$  = mean effective pressure per sq. in.,  $s$  = piston-speed in

ft. per min., and  $d$  = diam. of cylinder in inches; if  $s = 600$  ft. per min., which is approximately the speed of modern stationary engines, and  $P = 35$  lbs., which is an approximately average figure for the M.E.P. of single-cylinder engines, and of compound engines referred to the low-pressure cylinder, then  $\text{I.H.P.} = \frac{1}{2}d^2$ ; hence the rough-and-ready rule for horse-power given above: Square the diameter in inches and divide by 2. This applies to triple and quadruple expansion engines as well as to single cylinder and compound. For most economical loading, the M.E.P. referred to the low-pressure cylinder of compound engines is usually not greater than that of simple engines; for the greater economy is obtained by a greater number of expansions of steam of higher pressures, and the greater the number of expansions for a given initial pressure the lower the mean effective pressure. The following table gives approximately the figures of mean total and effec-

tive pressures for the different types of engines, together with the factor by which the square of the diameter is to be multiplied to obtain the horse-power at most economical loading, for a piston-speed of 600 ft. per minute.

Type of Engine.	Initial Absolute Steam-pressure.	Number of Expansions.	Terminal Absolute Press., lbs.	Ratio Mean Total to Initial Pressure.	Mean Total Pressure, lbs.	Total Back Pressure, Mean, lbs.	Mean Effective Pressure, lbs.	Piston-speed, ft. per min.	Horse-power = diam. <sup>2</sup> ×
-----------------	----------------------------------	-----------------------	--------------------------------	---------------------------------------	---------------------------	---------------------------------	-------------------------------	----------------------------	------------------------------------

Quadruple.....	200	25.	8	.169	33.8	2	31.8	"	.454

For any other piston-speed than 600 ft. per min., multiply the figures in the last column by the ratio of the piston-speed to 600 ft.

**Nominal Horse-power.**—The term “nominal horse-power” originated in the time of Watt, and was used to express approximately the power of an engine as calculated from its diameter, estimating the mean pressure in the cylinder at 7 lbs. above the atmosphere. It has long been obsolete in America, and is nearly obsolete in England.

**Horse-power Constant of a given Engine for a Fixed Speed** = product of its area of piston in square inches, length of stroke in feet, and number of single strokes per minute divided by 33,000, or  $\frac{Lan}{33,000} = C$ . The product of the mean effective pressure as found by the diagram and this constant is the indicated horse-power.

**Horse-power Constant of a given Engine for Varying Speeds** = product of its area of piston and length of stroke divided by 33,000. This multiplied by the mean effective pressure and by the number of single strokes per minute is the indicated horse-power.

**Horse-power Constant of any Engine of a given Diameter of Cylinder**, whatever the length of stroke = area of piston ÷ 33,000 = square of the diameter of piston in inches × .0000238. A table of constants derived from this formula is given below.

The constant multiplied by the piston-speed in feet per minute and by the M.E.P. gives the I.H.P.

**Errors of Indicators.**—The most common error is that of the spring, which may vary from its normal rating; the error may be determined by proper testing apparatus and allowed for. But after making this correction, even with the best work, the results are liable to variable errors which may amount to 2 or 3 per cent. See Barrus, Trans. A. S. M. E., v. 310; Denton, A. S. M. E., xi. 329; David Smith, U. S. N., Proc. Eng'g Congress, 1893, Marine Division.

Indicator “Rigs,” or Reducing-motions; Interpretation of Diagrams for Errors of Steam-distribution, etc. For these see circulars of manufacturers of Indicators; also works on the Indicator.

**Table of Engine Constants for Use in Figuring Horse-power.**—“Horse-power constant” for cylinders from 1 inch to 60 inches in diameter, advancing by 8ths, for one foot of piston-speed per minute and one pound of M.E.P. Find the diameter of the cylinder in the column at the side. If the diameter contains no fraction the constant will be found in the column headed Even Inches. If the diameter is not in even inches, follow the line horizontally to the column corresponding to the required fraction.

The constants multiplied by the piston-speed and by the M.E.P. give the horse-power.

Diameter of Cylinder.	Even Inches.	+ 1/8 or .125.	+ 1/4 or .25.	+ 3/8 or .375.	+ 1/2 or .5.	+ 5/8 or .625.	+ 3/4 or .75.	+ 7/8 or .875.

**To draw the Clearance-line on the Indicator-diagram,** the actual clearance not being known.—The clearance-line may be obtained approximately by drawing a straight line, *cbad*, across the compression curve, first having drawn *OX* parallel to the atmospheric line and 14.7 lbs. below. Measure from *a* the distance *ad*, equal to *cb*, and draw *YO* perpendicular to *OX* through *d*; then will *TB* divided by *AT* be the percentage of

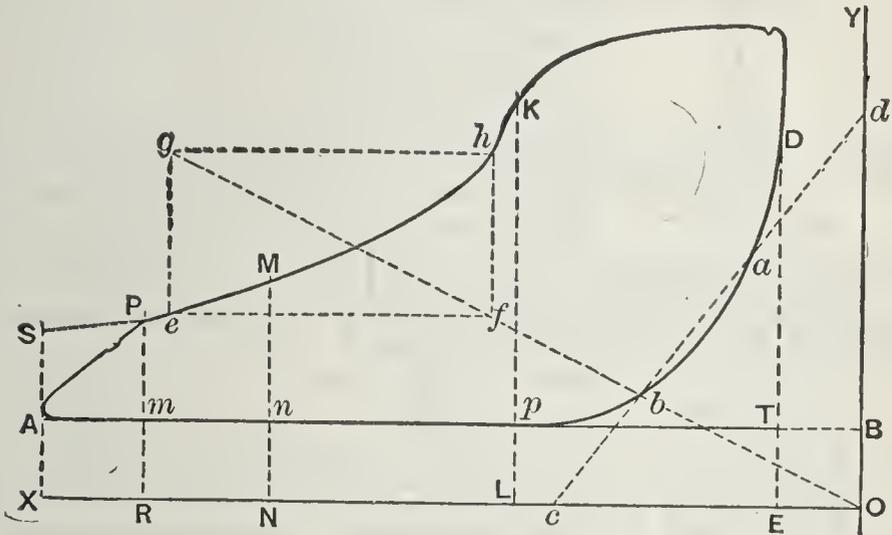

FIG. 139.

clearance. The clearance may also be found from the expansion-line by constructing a rectangle *efhg*, and drawing a diagonal *gf* to intersect the line *XO*. This will give the point *O*, and by erecting a perpendicular to *XO* we obtain a clearance-line *OY*.

Both these methods for finding the clearance require that the expansion and compression curves be hyperbolas. Prof. Carpenter (*Power*, Sept., 1893) says that with good diagrams the methods are usually very accurate, and give results which check substantially.

The Buckeye Engine Co., however, say that, as the results obtained are seldom correct, being sometimes too little, but more frequently too much, and as the indications from the two curves seldom agree, the operation has little practical value, though when a clearly defined and apparently undistorted compression curve exists of sufficient extent to admit of the application of the process, it may be relied on to give much more correct results than the expansion curve.

**To draw the Hyperbolic Curve on the Indicator-diagram.**—Select any point *I* in the actual curve, and from this point draw a

line perpendicular to the line *JB*, meeting the latter in the point *J*. The line *JB* may be the line of boiler-pressure, but this is not material; it may be drawn at any convenient height near the top of diagram and parallel to the atmospheric line. From *J* draw a diagonal to *K*, the latter point being the intersection of the vacuum and clearance lines; from *I* draw *IL* parallel with the atmospheric line. From *L*, the point of intersection of the diagonal *JK* and the horizontal line *IL*, draw the vertical line *LM*. The point *M* is the theoretical point of cut-off, and *LM* the cut-off line. Fix upon any number of points 1, 2, 3, etc., on the line *JB*, and from these points draw diagonals to *K*. From the intersection of these diagonals with *LM* draw horizontal lines, and from 1, 2, 3, etc., vertical lines. Where these lines meet will be points in the hyperbolic curve.

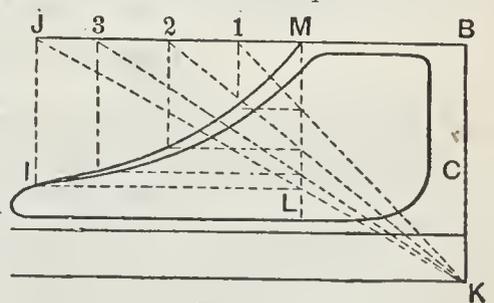

FIG. 140.

**Pendulum Indicator Rig.**—*Power* (Feb. 1893) gives a graphical representation of the errors in indicator-diagrams, caused by the use of in-

correct form of the pendulum rigging. It is shown that the "brumbo" pulley on the pendulum, to which the cord is attached, does not generally give as good a reduction as a simple pin attachment. When the end of the pendulum is slotted, working in a pin on the crosshead, the error is apt to be considerable at both ends of the card. With a vertical slot in a plate fixed to the crosshead, and a pin on the pendulum working in this slot, the reduction is perfect, when the cord is attached to a pin on the pendulum, a slight error being introduced if the brumbo pulley is used. With the connection between the pendulum and the crosshead made by means of a horizontal link, the reduction is nearly perfect, if the construction is such that the connecting link vibrates equally above and below the horizontal, and the cord is attached by a pin. If the link is horizontal at mid-stroke

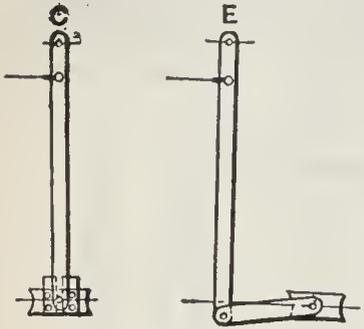

FIG. 141.

a serious error is introduced, which is magnified if a brumbo pulley also is used. The adjoining figures show the two forms recommended.

**Theoretical Water-consumption calculated from the Indicator-card.**—The following method is given by Prof. Carpenter (*Power*, Sept. 1893):  $p$  = mean effective pressure,  $l$  = length of stroke in feet,  $a$  = area of piston in square inches,  $a \div 144$  = area in square feet,  $c$  = percentage of clearance to the stroke,  $b$  = percentage of stroke at point where water rate is to be computed,  $n$  = number of strokes per minute,  $60n$  = number per hour,  $w$  = weight of a cubic foot of steam having a pressure as shown by the diagram corresponding to that at the point where water rate is required,  $w'$  = that corresponding to pressure at end of compression.

$$\text{Number of cubic feet per stroke} = l \left( \frac{b+c}{100} \right) \frac{a}{144}.$$

$$\text{Corresponding weight of steam per stroke in lbs.} = l \left( \frac{b+c}{100} \right) \frac{a}{144} w.$$

$$\text{Volume of clearance} = \frac{lca}{14,400}.$$

$$\text{Weight of steam in clearance} = \frac{lcaw'}{14,400}.$$

$$\text{Total weight of steam per stroke} \left. \begin{array}{l} \text{from diagram} \\ \text{per stroke} \end{array} \right\} = l \left( \frac{b+c}{100} \right) \frac{wa}{144} - \frac{lcaw'}{14,400} = \frac{la}{14,400} [(b+c)w - cw'].$$

$$\text{Total weight of steam from diagram per hour} \left. \begin{array}{l} \text{from diagram} \\ \text{per hour} \end{array} \right\} = \frac{60nla}{14,400} [(b+c)w - cw'].$$

The indicated horse-power is  $p l a n \div 33,000$ . Hence the steam-consumption per hour per indicated horse-power is

$$= \frac{\frac{60nla}{14,400} [(b+c)w - cw']}{\frac{p l a n}{33,000}} = \frac{137.50}{p} [(b+c)w - cw'].$$

Changing the formula to a rule, we have: To find the water rate from the indicator diagram at any point in the stroke.

**RULE.**—To the percentage of the entire stroke which has been completed by the piston at the point under consideration add the percentage of clearance. Multiply this result by the weight of a cubic foot of steam, having a pressure of that at the required point. Subtract from this the product of percentage of clearance multiplied by weight of a cubic foot of steam having a pressure equal to that at the end of the compression. Multiply this result by 137.50 divided by the mean effective pressure.\*

**NOTE.**—This method only applies to points in the expansion curve or between cut-off and release.

\* For compound or triple-expansion engines read: divided by the equivalent mean effective pressure, on the supposition that all work is done in one cylinder.

The beneficial effect of compression in reducing the water-consumption of an engine is clearly shown by the formula. If the compression is carried to such a point that it produces a pressure equal to that at the point under consideration, the weight of steam per cubic foot is equal, and  $w = w'$ . In this case the effect of clearance entirely disappears, and the formula becomes  $\frac{137.5}{p}(bw)$ .

In case of no compression,  $w'$  becomes zero, and the water-rate =

$$\frac{137.5}{p} \cdot [(b + c)w].$$

Prof. Denton (Trans. A. S. M. E., xiv. 1363) gives the following table of theoretical water-consumption for a perfect Mariotte expansion with steam at 150 lbs. above atmosphere, and 2 lbs. absolute back pressure :

Ratio of Expansion, $r$ .	M.E.P., lbs. per sq. in.	Lbs. of Water per hour per horse-power, $W$ .
10	52.4	9.68
15	38.7	8.74
20	30.9	8.20
25	25.9	7.84
30	22.2	7.63
35	19.5	7.45

The difference between the theoretical water-consumption found by the formula and the actual consumption as found by test represents "water not accounted for by the indicator," due to cylinder condensation, leakage through ports, radiation, etc.

**Leakage of Steam.**—Leakage of steam, except in rare instances, has so little effect upon the lines of the diagram that it can scarcely be detected. The only satisfactory way to determine the tightness of an engine is to take it when not in motion, apply a full boiler-pressure to the valve, placed in a closed position, and to the piston as well, which is blocked for the purpose at some point away from the end of the stroke, and see by the eye whether leakage occurs. The indicator-cocks provide means for bringing into view steam which leaks through the steam-valves, and in most cases that which leaks by the piston, and an opening made in the exhaust-pipe or observations at the atmospheric escape-pipe, are generally sufficient to determine the fact with regard to the exhaust-valves.

The steam accounted for by the indicator should be computed for both the cut-off and the release points of the diagram. If the expansion-line departs much from the hyperbolic curve a very different result is shown at one point from that shown at the other. In such cases the extent of the loss occasioned by cylinder condensation and leakage is indicated in a much more truthful manner at the cut-off than at the release. (Tabor Indicator Circular.)

## COMPOUND ENGINES.

### Compound, Triple- and Quadruple-expansion Engines.

—A compound engine is one having two or more cylinders, and in which the steam after doing work in the first or high-pressure cylinder completes its expansion in the other cylinder or cylinders.

The term "compound" is commonly restricted; however, to engines in which the expansion takes place in two stages only—high and low pressure, the terms triple-expansion and quadruple-expansion engines being used when the expansion takes place respectively in three and four stages. The number of cylinders may be greater than the number of stages of expansion, for constructive reasons; thus in the compound or two-stage expansion engine the low-pressure stage may be effected in two cylinders so as to obtain the advantages of nearly equal sizes of cylinders and of three cranks at angles of 120°. In triple-expansion engines there are frequently two low-pressure cylinders, one of them being placed tandem with the high-pressure, and the other with the intermediate cylinder, as in mill engines with two cranks at 90°. In the triple-expansion engines of the steamers *Campania* and *Lucania*,

with three cranks at 120°, there are five cylinders, two high, one intermediate, and two low, the high-pressure cylinders being tandem with the low.

**Advantages of Compounding.**—The advantages secured by dividing the expansion into two or more stages are twofold: 1. Reduction of wastes of steam by cylinder-condensation, clearance, and leakage; 2. Dividing the pressures on the cranks, shafts, etc., in large engines so as to avoid excessive pressures and consequent friction. The diminished loss by cylinder-condensation is effected by decreasing the range of temperature of the metal surfaces of the cylinders, or the difference of temperature of the steam at admission and exhaust. When high-pressure steam is admitted into a single-cylinder engine a large portion is condensed by the comparatively cold metal surfaces; at the end of the stroke and during the exhaust the water is re-evaporated, but the steam so formed escapes into the atmosphere or into the condenser, doing no work; while if it is taken into a second cylinder, as in a compound engine, it does work. The steam lost in the first cylinder by leakage and clearance also does work in the second cylinder. Also, if there is a second cylinder, the temperature of the steam exhausted from the first cylinder is higher than if there is only one cylinder, and the metal surfaces therefore are not cooled to the same degree. The difference in temperatures and in pressures corresponding to the work of steam of 150 lbs. gauge-pressure expanded 20 times, in one, two, and three cylinders, is shown in the following table, by W. H. Weightman, *Am. Mach.*, July 28, 1892:

	Single Cylinder.	Compound Cylinders.		Triple-expansion Cylinders.

**“Woolf” and Receiver Types of Compound Engines.**—

The compound steam-engine, consisting of two cylinders, is reducible to two forms, 1, in which the steam from the h.p. cylinder is exhausted direct into the l. p. cylinder, as in the Woolf engine; and 2, in which the steam from the h. p. cylinder is exhausted into an intermediate reservoir, whence the steam is supplied to, and expanded in, the l. p. cylinder, as in the “receiver-engine.”

If the steam be cut off in the first cylinder before the end of the stroke, the total ratio of expansion is the product of the ratio of expansion in the first cylinder, into the ratio of the volume of the second to that of the first cylinder; that is, the product of the two ratios of expansion.

Thus, let the areas of the first and second cylinders be as 1 to 3½, the strokes being equal, and let the steam be cut off in the first at ½ stroke; then

Expansion in the 1st cylinder.....	1 to 2
“ “ “ 2d “ .....	1 to 3½

Total or combined expansion, the product of the two ratios... 1 to 7

**Woolf Engine, without Clearance—Ideal Diagrams.**—

The diagrams of pressure of an ideal Woolf engine are shown in Fig. 142, as they would be described by the indicator, according to the arrows. In these diagrams *pq* is the atmospheric line, *mn* the vacuum line, *cd* the admission

line,  $dg$  the hyperbolic curve of expansion in the first cylinder, and  $gh$  the consecutive expansion-line of back pressure for the return-stroke of the first piston, and of positive pressure for the steam-stroke of the second piston. At the point  $h$ , at the end of the stroke of the second piston, the steam is exhausted into the condenser, and the pressure falls to the level of perfect vacuum,  $mn$ .

The diagram of the second cylinder, below  $gh$ , is characterized by the absence of any specific period of admission; the whole of the steam-line  $gh$  being expansional, generated by the expansion of the initial body of steam contained in the first cylinder into the second. When the return-stroke is completed, the whole of the steam transferred from the first is shut into the second cylinder. The final pressure and volume of the steam in the second cylinder are the same as if the whole of the initial steam had been admitted at once into the second cylinder, and then expanded to the end of the stroke in the manner of a single-cylinder engine.

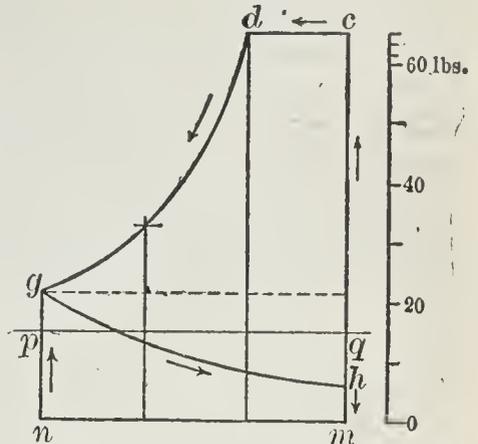

FIG. 142.—WOOLF ENGINE—IDEAL INDICATOR-DIAGRAMS.

The net work of the steam is also the same, according to both distributions. **Receiver-engine, without Clearance—Ideal Diagrams.**—In the ideal receiver-engine the pistons of the two cylinders are connected to cranks at right angles to each other on the same shaft. The receiver takes the steam exhausted from the first cylinder and supplies it to the second, in which the steam is cut off and then expanded to the end of the stroke. On the assumption that the initial pressure in the second cylinder is equal to the final pressure in the first, and of course equal to the pressure in the receiver, the volume cut off in the second cylinder must be equal to the volume of the first cylinder, for the second cylinder must admit as much steam at each stroke as is discharged from the first cylinder.

In Fig. 143  $cd$  is the line of admission and  $hg$  the exhaust-line for the first

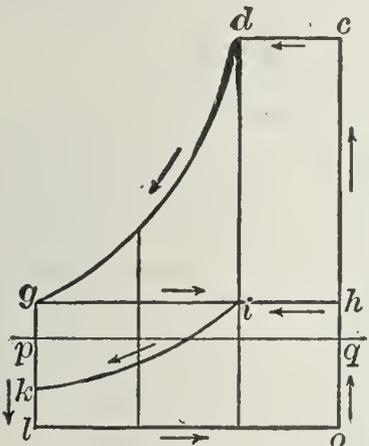

FIG. 143.—RECEIVER-ENGINE, IDEAL INDICATOR-DIAGRAMS.

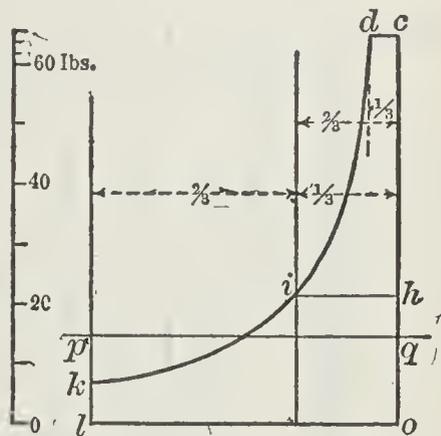

FIG. 144.—RECEIVER ENGINE, IDEAL DIAGRAMS REDUCED AND COMBINED.

cylinder; and  $dg$  is the expansion-curve and  $pq$  the atmospheric line. In the region below the exhaust-line of the first cylinder, between it and the line of perfect vacuum,  $ol$ , the diagram of the second cylinder is formed;  $hi$ , the second line of admission, coincides with the exhaust-line  $hg$  of the first cylinder, showing in the ideal diagram no intermediate fall of pressure, and  $ik$  is the expansion-curve. The arrows indicate the order in which the diagrams are formed.

In the action of the receiver-engine, the expansive working of the steam, though clearly divided into two consecutive stages, is, as in the Woolf engine, essentially continuous from the point of cut-off in the first cylinder to the end of the stroke of the second cylinder, where it is delivered to the condenser; and the first and second diagrams may be placed together and

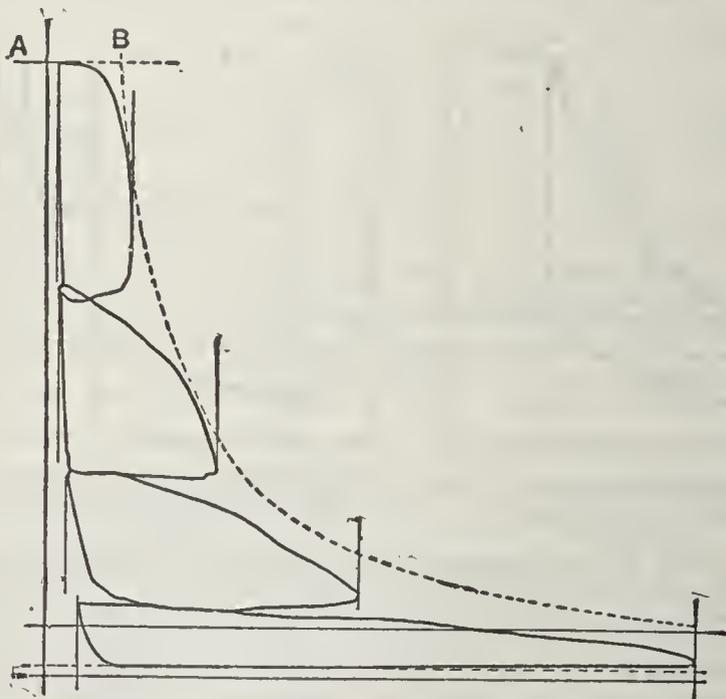

combined to form a continuous diagram. For this purpose take the second diagram as the basis of the combined diagram, namely, *hiklo*, Fig. 144. The period of admission, *hi*, is one third of the stroke, and as the ratios of the cylinders are as 1 to 3, *hi* is also the proportional length of the first diagram as applied to the second. Produce *oh* upwards, and set off *oc* equal to the total height of the first diagram above the vacuum-line; and, upon the shortened base *hi*, and the height *hc*, complete the first diagram with the steam-line *cd*, and the expansion-line *di*.

It is shown by Clark (S. E., p. 432, *et seq.*) in a series of arithmetical calculations, that the receiver-engine is an elastic system of compound engine, in which considerable latitude is afforded for adapting the pressure in the receiver to the demands of the second cylinder, without considerably diminishing the effective work of the engine. In the Woolf engine, on the contrary, it is of much importance that the intermediate volume of space between the first and second cylinders, which is the cause of an intermediate fall of pressure, should be reduced to the lowest practicable amount.

Supposing that there is no loss of steam in passing through the engine, by cooling and condensation, it is obvious that whatever steam passes through the first cylinder must also find its way through the second cylinder. By varying, therefore, in the receiver-engine, the period of admission in the second cylinder, and thus also the volume of steam admitted for each stroke, the steam will be measured into it at a higher pressure and of a less bulk, or at a lower pressure and of a greater bulk; the pressure and density naturally adjusting themselves to the volume that the steam from the receiver is permitted to occupy in the second cylinder. With a sufficiently restricted admission, the pressure in the receiver may be maintained at the pressure of the steam as exhausted from the first cylinder. On the contrary, with a wider admission, the pressure in the receiver may fall or "drop" to three fourths or even one half of the pressure of the exhaust steam from the first cylinder.

(For a more complete discussion of the action of steam in the Woolf and receiver engines, see Clark on the Steam-engine.)

**Combined Diagrams of Compound Engines.**—The only way of making a correct combined diagram from the indicator-diagrams of the several cylinders in a compound engine is to set off all the diagrams on the same horizontal scale of volumes, adding the clearances to the cylinder ca-

pacities proper. When this is attended to, the successive diagrams fall exactly into their right places relatively to one another, and would compare properly with any theoretical expansion-curve. (Prof. A. B. W. Kennedy, Proc. Inst. M. E., Oct. 1886.)

This method of combining diagrams is commonly adopted, but there are objections to its accuracy, since the whole quantity of steam consumed in the first cylinder at the end of the stroke is not carried forward to the second, but a part of it is retained in the first cylinder for compression. For a method of combining diagrams in which compression is taken account of, see discussions by Thomas Mudd and others, in Proc. Inst. M. E., Feb., 1887, p. 48. The usual method of combining diagrams is also criticised by Frank H. Ball as inaccurate and misleading (*Am. Mach.*, April 12, 1894; *Trans. A. S. M. E.*, xiv. 1405, and xv. 403).

Figure 145 shows a combined diagram of a quadruple-expansion engine, drawn according to the usual method, that is, the diagrams are first reduced in length to relative scales that correspond with the relative piston-displacement of the three cylinders. Then the diagrams are placed at such distances from the clearance-line of the proposed combined diagram as to correctly represent the clearance in each cylinder.

**Calculated Expansions and Pressures in Two-cylinder Compound Engines.** (James Tribe, *Am. Mach.*, Sept. & Oct. 1891.)

The probable percentage of loss, line 3, is thus explained: There is always a loss of heat due to condensation, and which increases with the pressure of steam. The exact percentage cannot be predetermined, as it depends largely upon the quality of the non-conducting covering used on the cylinder, receiver, and pipes, etc., but will probably be about as shown.

**Proportions of Cylinders in Compound Engines.**—Authorities differ as to the proportions by volume of the high and low pressure cylinders  $v$  and  $V$ . Thus Grashof gives  $V \div v = 0.85 \sqrt{r}$ ; Hrabak,  $0.90 \sqrt{r}$ ;

Werner,  $\sqrt{r}$ ; and Rankine,  $\sqrt[3]{r^2}$ ,  $r$  being the ratio of expansion. Busley makes the ratio dependent on the boiler-pressure thus:

Lbs. per sq. in.....	60	90	105	120
$V + v$ .....	= 3	4	4.5	5

(See Seaton's Manual, p. 95, etc., for analytical method; Sennett, p. 496, etc.; Clark's Steam-engine, p. 445, etc; Clark, Rules, Tables, Data, p. 849, etc.)

Mr. J. McFarlane Gray states that he finds the mean effective pressure in the compound engine reduced to the low-pressure cylinder to be approximately the square root of 6 times the boiler-pressure.

**Approximate Horse-power of a Modern Compound Marine-engine.** (Seaton.)—The following rule will give approximately the horse-power developed by a compound engine made in accordance with

modern marine practice. Estimated H.P. =  $\frac{D^2 \times \sqrt{p} \times R \times S}{8500}$ .

$D$  = diameter of l.p. cylinder;  $p$  = boiler-pressure by gauge;  
 $R$  = revs. per min.;  $S$  = stroke of piston in feet.

**Ratio of Cylinder Capacity in Compound Marine Engines.** (Seaton.)—The low-pressure cylinder is the measure of the power of a compound engine, for so long as the initial steam-pressure and rate of expansion are the same, it signifies very little, so far as total power only is concerned, whether the ratio between the low and high-pressure cylinders is 3 or 4; but as the power developed should be nearly equally divided between the two cylinders, in order to get a good and steady working engine, there is a necessity for exercising a considerable amount of discretion in fixing on the ratio.

In choosing a particular ratio the objects are to divide the power evenly and to avoid as much as possible "drop" and high initial strain.

If increased economy is to be obtained by increased boiler-pressures, the rate of expansion should vary with the initial pressure, so that the pressure at which the steam enters the condenser should remain constant. In this case, with the ratio of cylinders constant, the cut-off in the high-pressure cylinder will vary inversely as the initial pressure.

Let  $R$  be the ratio of the cylinders;  $r$ , the rate of expansion;  $p_1$  the initial pressure: then cut-off in high-pressure cylinder =  $R \div r$ ;  $r$  varies with  $p_1$ , so that the terminal pressure  $p_n$  is constant, and consequently  $r = p_1 \div p_n$ ; therefore, cut-off in high-pressure cylinder =  $R \times p_n \div p_1$ .

**Ratios of Cylinders as Found in Marine Practice.**—The rate of expansion may be taken at one tenth of the boiler-pressure (or about one twelfth the absolute pressure), to work economically at full speed. Therefore, when the diameter of the low-pressure cylinder does not exceed 100 inches, and the boiler-pressure 70 lbs., the ratio of the low-pressure to the high-pressure cylinder should be 3.5; for a boiler-pressure of 80 lbs., 3.75; for 90 lbs., 4.0; for 100 lbs., 4.5. If these proportions are adhered to, there will be no need of an expansion-valve to either cylinder. If, however, to avoid "drop," the ratio be reduced, an expansion-valve should be fitted to the high-pressure cylinder.

Where economy of steam is not of first importance, but rather a large power, the ratio of cylinder capacities may with advantage be decreased, so that with a boiler-pressure of 100 lbs. it may be 3.75 to 4.

In tandem engines there is no necessity to divide the work equally. The ratio is generally 4, but when the steam-pressure exceeds 90 lbs. absolute 4.5 is better, and for 100 lbs. 5.0.

When the power requires that the l. p. cylinder shall be more than 100 in. diameter, it should be divided in two cylinders. In this case the ratio of the combined capacity of the two l. p. cylinders to that of the h. p. may be 3.0 for 85 lbs. absolute, 3.4 for 95 lbs., 3.7 for 105 lbs., and 4.0 for 115 lbs.

**Receiver Space in Compound Engines** should be from 1 to 1.5 times the capacity of the high-pressure cylinder, when the cranks are at an angle of from 90° to 120°. When the cranks are at 180° or nearly this, the space may be very much reduced. In the case of triple-compound engines, with cranks at 120°, and the intermediate cylinder leading the high-pressure, a very small receiver will do. The pressure in the receiver should never exceed half the boiler-pressure. (Seaton.)

**Formula for Calculating the Expansion and the Work of Steam in Compound Engines.**

(Condensed from Clark on the "Steam-engine.")

- a** = area of the first cylinder in square inches;
- a'** = area of the second cylinder in square inches;
- r** = ratio of the capacity of the second cylinder to that of the first;
- L** = length of stroke in feet, supposed to be the same for both cylinders;
- l** = period of admission to the first cylinder in feet, excluding clearance;
- c** = clearance at each end of the cylinders, in parts of the stroke, in feet;
- L'** = length of the stroke plus the clearance, in feet;
- l'** = period of admission plus the clearance, in feet;
- s** = length of a given part of the stroke of the second cylinder, in feet;
- P** = total initial pressure in the first cylinder, in lbs. per square inch, supposed to be uniform during admission;
- P'** = total pressure at the end of the given part of the stroke **s**;
- p** = average total pressure for the whole stroke;
- R** = nominal ratio of expansion in the first cylinder, or  $L + l$ ;
- R'** = actual ratio of expansion in the first cylinder, or  $L' + l'$ ;
- R''** = actual combined ratio of expansion, in the first and second cylinders together;
- n** = ratio of the final pressure in the first cylinder to any intermediate fall of pressure between the first and second cylinders;
- N** = ratio of the volume of the intermediate space in the Woolf engine, reckoned up to, and including the clearance of, the second piston, to the capacity of the first cylinder plus its clearance. The value of **N** is correctly expressed by the actual ratio of the volumes as stated, on the assumption that the intermediate space is a vacuum when it receives the exhaust-steam from the first cylinder. In point of fact, there is a residuum of unexhausted steam in the intermediate space, at low pressure, and the value of **N** is thereby practically reduced below the ratio here stated.  $N = \frac{n}{n-1} - 1$ .

**w** = whole net work in one stroke, in foot-pounds.

Ratio of expansion in the second cylinder:

In the Woolf engine,  $\frac{\left(r \frac{L}{L'}\right) + N}{1 + N}$ ;

In the receiver-engine,  $\frac{(n-1)r}{n}$ .

Total actual ratio of expansion = product of the ratios of the three consecutive expansions, in the first cylinder, in the intermediate space, and in the second cylinder,

In the Woolf engine,  $R' \left(r \frac{L}{L'} + N\right)$ ;

In the receiver-engine,  $r \frac{L'}{l'}$ , or  $rR'$ .

Combined ratio of expansion behind the pistons =  $\frac{n-1}{n} rR' = R''$ .

Work done in the two cylinders for one stroke, with a given cut-off and a given combined actual ratio of expansion:

Woolf engine,  $w = aP[l'(1 + \text{hyp log } R'') - c]$ ;

Receiver engine,  $w = aP\left[l'(1 + \text{hyp log } R'') - c\left(1 + \frac{r-1}{R'}\right)\right]$ ,

when there is no intermediate fall of pressure.

When there is an intermediate fall, when the pressure falls to  $\frac{3}{4}$ ,  $\frac{2}{3}$ ,  $\frac{1}{2}$  of the final pressure in the 1st cylinder, the reduction of work is 0.2%, 1.0%, 4.6% of that when there is no fall.

Total work in the two cylinders of a receiver-engine, for one stroke for any intermediate fall of pressure,

$$w = aP \left[ v \left( \frac{n+1}{n} + \text{hyp log } R'' \right) - c \left( 1 + \frac{(n-1)(r-1)}{nR'} \right) \right].$$

EXAMPLE.—Let  $a = 1$  sq. in.,  $P = 63$  lbs.,  $v = 2.42$  ft.,  $n = 4$ ,  $R'' = 5.969$ ,  $c = .42$  ft.,  $r = 3$ ,  $R' = 2.653$ ;

$$w = 1 \times 63 \left[ 2.42(5/4 \text{ hyp log } 5.969) - .42 \left( 1 + \frac{3 \times 2}{4 \times 2.653} \right) \right] = 421.55 \text{ ft.-lbs.}$$

**Calculation of Diameters of Cylinders** of a compound condensing engine of 2000 H.P. at a speed of 700 feet per minute, with 100 lbs. boiler-pressure.

100 lbs. gauge-pressure = 115 absolute, less drop of 5 lbs. between boiler and cylinder = 110 lbs. initial absolute pressure. Assuming terminal pressure in l. p. cylinder = 6 lbs., the total expansion of steam in both cylinders =  $110 \div 6 = 18.33$ . Hyp log 18.33 = 2.909. Back pressure in l. p. cylinder, 3 lbs. absolute.

The following formulæ are used in the calculation of each cylinder :

$$(1) \text{ Area of cylinder} = \frac{\text{H.P.} \times 33,000}{\text{M.E.P.} \times \text{piston-speed}}$$

(2) Mean effective pressure = mean total pressure — back pressure.

(3) Mean total pressure = terminal pressure  $\times$  (1 + hyp log  $R$ ).

(4) Absolute initial pressure = absolute terminal pressure  $\times$  ratio of expansion.

First calculate the area of the low-pressure cylinder as if all the work were done in that cylinder.

From (3), mean total pressure =  $6 \times (1 + \text{hyp log } 18.33) = 23.454$  lbs.

From (2), mean effective pressure =  $23.454 - 3 = 20.454$  lbs.

From (1), area of cylinder =  $\frac{2000 \times 33,000}{20.454 \times 700} = 4610$  sq. ins. = 76.6 ins. diam.

If half the work, or 1000 H.P., is done in the l. p. cylinder the M.E.P. will be half that found above, or 10.227 lbs., and the mean total pressure  $10.227 + 3 = 13.227$  lbs.

From (3),  $1 + \text{hyp log } R = 13.227 \div 6 = 2.2045$ .

Hyp log  $R = 1.2045$ , whence  $R$  in l. p. cyl. = 3.335.

From (4),  $3.335 \times 6 = 20.01$  lbs. initial pressure in l. p. cyl. and terminal pressure in h. p. cyl., assuming no drop between cylinders.

$110 \div 20.01 = 5.497$ ,  $R$  in h. p. cyl.

From (3), mean total pres. in h. p. cyl. =  $20.01 \times (1 + \text{hyp log } 5.497) = 54.11$ .

From (2),  $54.11 - 20.01 = 34.10$ , M.E.P. in h. p. cyl.

From (1), area of h. p. cyl. =  $\frac{1000 \times 33,000}{700 \times 34.1} = 1382$  sq. ins. = 42 ins. diam.

Cylinder ratio =  $4610 \div 1382 = 3.336$ .

The area of the h. p. cylinder may be found more directly by dividing the area of the l. p. cyl. by the ratio of expansion in that cylinder.  $4610 \div 3.335 = 1382$  sq. ins.

In the above calculation no account is taken of clearance, of compression, of drop between cylinders, nor of area of piston-rods. It also assumes that the diagram in each cylinder is the full theoretical diagram, with a horizontal steam-line and a hyperbolic expansion line, with no allowance for rounding of the corners. To make allowance for these, the mean effective pressure in each cylinder must be multiplied by a diagram factor, or the ratio of the area of an actual diagram of the class of engine considered, with the given initial and terminal pressures, to the area of the theoretical diagram. Such diagram factors will range from 0.6 to 0.94, as in the table on p. 745.

**Best Ratios of Cylinders.**—The question what is the best ratio of areas of the two cylinders of a compound engine is still (1901), a disputed one, but there appears to be an increasing tendency in favor of large ratios, even as great as 7 or 8 to 1, with considerable terminal drop in the high-pressure cylinder. A discussion of the subject, together with a description of a new method of drawing theoretical diagrams of multiple-expansion engines, taking into consideration drop, clearance, and compression, will be found in a paper by Bert C. Ball, in Trans. A. S. M. E., xxi. 1002,

## TRIPLE-EXPANSION ENGINES.

**Proportions of Cylinders.**—H. H. Suplee, *Mechanics*, Nov. 1887, gives the following method of proportioning cylinders of triple-expansion engines:

As in the case of compound engines the diameter of the low-pressure cylinder is first determined, being made large enough to furnish the entire power required at the mean pressure due to the initial pressure and expansion ratio given; and then this cylinder is only given pressure enough to perform one third of the work, and the other cylinders are proportioned so as to divide the other two thirds between them.

Let us suppose that an initial pressure of 150 lbs. is used and that 900 H.P. is to be developed at a piston-speed of 800 ft. per min., and that an expansion ratio of 16 is to be reached with an absolute back pressure of 2 lbs.

The theoretical M.E.P. with an absolute initial pressure of  $150 + 14.7 = 164.7$  lbs. initial at 16 expansions is

$$\frac{P(1 + \text{hyp log } 16)}{16} = 164.7 \times \frac{3.7726}{16} = 38.83,$$

less 2 lbs. back pressure,  $= 38.83 - 2 = 36.83$ .

In practice only about 0.7 of this pressure is actually attained, so that  $36.83 \times 0.7 = 25.781$  lbs. is the M.E.P. upon which the engine is to be proportioned.

To obtain 900 H.P. we must have  $33,000 \times 900 = 29,700,000$  foot-pounds, and this divided by the mean pressure (25.78) and by the speed in feet (800) will give 1440 sq. in. for the area of the l. p. cylinder, about equivalent to 43 in. diam.

NOW as one third of the work is to be done in the l. p. cylinder, the M.E.P. in it will be  $25.78 \div 3 = 8.59$  lbs.

The cut-off in the high-pressure cylinder is generally arranged to cut off at 0.6 of the stroke, and so the ratio of the h. p. to the l. p. cylinder is equal to  $16 \times 0.6 = 9.6$ , and the h. p. cylinder will be  $1440 \div 9.6 = 150$  sq. in. area, or about 14 in. diameter, and the M.E.P. in the h. p. cylinder is equal to  $9.6 \times 8.59 = 82.46$  lbs.

If the intermediate cylinder is made a mean size between the other two, its size would be determined by dividing the area of the l. p. cylinder by the square root of the ratio between the low and the high; but in practice this is found to give a result too large to equalize the stresses, so that instead the area of the int. cylinder is found by dividing the area of the l. p. piston by 1.1 times the square root of the ratio of l. p. to h. p. cylinder, which in this case is  $1440 \div (1.1 \sqrt{9.6}) = 422.5$  sq. in., or a little more than 23 in. diam.

The choice of expansion ratio is governed by the initial pressure, and is generally chosen so that the terminal pressure in the l. p. cylinder shall be about 10 lbs. absolute.

**Formulae for Proportioning Cylinder Areas of Triple-Expansion Engines.**—The following formulae are based on the method of first finding the cylinder areas that would be required if an ideal hyperbolic diagram were obtainable from each cylinder, with no clearance, compression, wire-drawing, drop by free expansion in receivers, or loss by cylinder condensation, assuming equal work to be done in each cylinder, and then dividing the areas thus found by a suitable diagram factor, such as those given on page 745, expressing the ratio which the area of an actual diagram, obtained in practice from an engine of the type under consideration, bears to the ideal or theoretical diagram. It will vary in different classes of engine and in different cylinders of the same engine, usual values ranging from 0.6 to 0.9. When any one of the three stages of expansion takes place in two cylinders, the combined area of these cylinders equals the area found by the formulae.

Given the required H.P. of an engine, its speed and length of stroke, and the assumed diagram factors  $F_1, F_2, F_3$  for the three cylinders, the areas of the cylinders may be found by using formulæ (11), (12), and (14), and the values of  $P_1, P_2,$  and  $P_3$  in the above table.

**A Common Rule for Proportioning the Cylinders** of multiple-expansion engines is: for two-cylinder compound engines, the cylinder ratio is the square root of the number of expansions, and for triple-expansion engines the ratios of the high to the intermediate and of the intermediate to the low are each equal to the cube root of the number of expansions, the ratio of the high to the low being the product of the two ratios, that is, the square of the cube root of the number of expansions. Applying this rule to the pressures above given, assuming a terminal pressure (absolute) of 10 lbs. and 8 lbs. respectively, we have, for triple-expansion engines:

Boiler-pressure (Absolute).	Terminal Pressure, 10 lbs.		Terminal Pressure, 8 lbs.	
	No. of Expansions.	Cylinder Ratios, areas.	No. of Expansions.	Cylinder Ratios, areas.
130.	13	1 to 2.35 to 5.53	16 $\frac{1}{4}$	1 to 2.53 to 6.42
140	14	1 to 2.41 to 5.81	17 $\frac{1}{2}$	1 to 2.60 to 6.74
150	15	1 to 2.47 to 6.08	18 $\frac{3}{4}$	1 to 2.66 to 7.06
160	16	1 to 2.52 to 6.35	20	1 to 2.71 to 7.37

The ratio of the diameters is the square root of the ratios of the areas, and the ratio of the diameters of the first and third cylinders is the same as the ratio of the areas of first and second.

Seaton, in his *Marine Engineering*, says: When the pressure of steam employed exceeds 115 lbs. absolute, it is advisable to employ three cylinders, through each of which the steam expands in turn. The ratio of the low-pressure to high-pressure cylinder in this system should be 5, when the steam-pressure is 125 lbs. absolute; when 135 lbs. absolute, 5.4; when 145 lbs. absolute, 5.8; when 155 lbs. absolute, 6.2; when 165 lbs. absolute, 6.6. The ratio of low-pressure to intermediate cylinder should be about one half that between low-pressure and high-pressure, as given above. That is, if the ratio of l. p. to h. p. is 6, that of l. p. to int. should be about 3, and consequently that of int. to h. p. about 2. In practice the ratio of int. to h. p. is nearly 2.25, so that the diameter of the int. cylinder is 1.5 that of the h. p. The introduction of the triple-compound engine has admitted of ships being propelled at higher rates of speed than formerly obtained without exceeding the consumption of fuel of similar ships fitted with ordinary compound engines; in such cases the higher power to obtain the speed has been developed by decreasing the rate of expansion, the low-pressure cylinder being only 6 times the capacity of the high-pressure, with a working pressure of 170 lbs. absolute. It is now a very general practice to make the diameter of the low pressure cylinder equal to the sum of the diameters of the h. p. and int. cylinders; hence,

$$\begin{aligned} \text{Diameter of int. cylinder} &= 1.5 \text{ diameter of h. p. cylinder;} \\ \text{Diameter of l. p. cylinder} &= 2.5 \text{ diameter of h. p. cylinder.} \end{aligned}$$

In this case the ratio of l. p. to h. p. is 6.25; the ratio of int. to h. p. is 2.25; and ratio of l. p. to int. is 2.78.

**Ratios of Cylinders for Different Classes of Engines.** (Proc. Inst. M. E., Feb. 1887, p. 36.)—As to the best ratios for the cylinders in a triple engine there seems to be great difference of opinion. Considerable latitude, however, is due to the requirements of the case, inasmuch as it would not be expected that the same ratio would be suitable for an economical land engine, where the space occupied and the weight were of minor importance, as in a war-ship, where the conditions were reversed. In the land engine, for example, a theoretical terminal pressure of about 7 lbs. above absolute vacuum would probably be aimed at, which would give a ratio of capacity of high pressure to low pressure of 1 to 8 $\frac{1}{2}$  or 1 to 9; whilst in a war-ship a terminal pressure would be required of 12 to 13 lbs. which would need a ratio of capacity of 1 to 5; yet in both these instances the cylinders were correctly proportioned and suitable to the requirements of the case. It is obviously unwise, therefore, to introduce any hard-and-fast rule.

**Types of Three-stage Expansion Engines.**—1. Three cranks at 120 deg. 2. Two cranks with 1st and 2d cylinders tandem. 3. Two cranks with 1st and 3d cylinders tandem. The most common type is the first, with cylinders arranged in the sequence high, intermediate, low.

**Sequence of Cranks.**—Mr. Wyllie (Proc. Inst. M. E., 1887) favors the sequence high, low, intermediate, while Mr. Mudd favors high, intermediate, low. The former sequence, high, low, intermediate, gave an approximately horizontal exhaust-line, and thus minimizes the range of temperature and the initial load; the latter sequence, high, intermediate, low, increased the range and also the load.

Mr. Morrisou, in discussing the question of sequence of cranks, presented a diagram showing that with the cranks arranged in the sequence high, low, intermediate, the mean compression into the receiver was  $19\frac{1}{2}$  per cent of the stroke; with the sequence high, intermediate, low, it was 57 per cent.

In the former case the compression was just what was required to keep the receiver-pressure practically uniform; in the latter case the compression caused a variation in the receiver-pressure to the extent sometimes of  $22\frac{1}{2}$  lbs.

**Velocity of Steam through Passages in Compound Engines.** (Proc. Inst. M. E., Feb. 1887.)—In the SS. *Para*, taking the area of the cylinder multiplied by the piston-speed in feet per second and dividing by the area of the port the velocity of the initial steam through the high-pressure cylinder port would be about 100 feet per second; the exhaust would be about 90. In the intermediate cylinder the initial steam had a velocity of about 180, and the exhaust of 120. In the low-pressure cylinder the initial steam entered through the port with a velocity of 250, and in the exhaust-port the velocity was about 140 feet per second.

### QUADRUPLE-EXPANSION ENGINES.

H. H. Suplee (Trans. A. S. M. E., x, 583) states that a study of 14 different quadruple-expansion engines, nearly all intended to be operated at a pressure of 180 lbs. per sq. in., gave average cylinder ratios of 1 to 2, to 3.78, to 7.70, or nearly in the proportions 1, 2, 4, 8.

If we take the ratio of areas of any two adjoining cylinders as the fourth root of the number of expansions, the ratio of the 1st to the 4th will be the cube of the fourth root. On this basis the ratios of areas for different pressures and rates of expansion will be as follows:

Gauge-pressures.	Absolute Pressures.	Terminal Pressures.	Ratio of Expansion.	Ratios of Areas of Cylinders.
160	175	12	14.6	1 : 1.95 : 3.81 : 7.43
		10	17.5	1 : 2.05 : 4.18 : 8.55
		8	21.9	1 : 2.16 : 4.68 : 10.12
180	195	12	16.2	1 : 2.01 : 4.02 : 8.07
		10	19.5	1 : 2.10 : 4.42 : 9.28
		8	24.4	1 : 2.22 : 4.94 : 10.98
200	215	12	17.9	1 : 2.06 : 4.23 : 8.70
		10	21.5	1 : 2.15 : 4.64 : 9.98
		8	26.9	1 : 2.28 : 5.19 : 11.81
220	235	12	19.6	1 : 2.10 : 4.43 : 9.31
		10	23.5	1 : 2.20 : 4.85 : 10.67
		8	29.4	1 : 2.33 : 5.42 : 12.62

Seaton says: When the pressure of steam employed exceeds 190 lbs. absolute, four cylinders should be employed, with the steam expanding through each successively; and the ratio of l. p. to h. p. should be at least 7.5, and if economy of fuel is of prime consideration it should be 8; then the ratio of first intermediate to h. p. should be 1.8, that of second intermediate to first int. 2, and that of l. p. to second int. 2.2.

In a paper read before the North East Coast Institution of Engineers and Shipbuilders, 1890, William Russell Cummins advocates the use of a four-cylinder engine with four cranks as being more suitable for high speeds than the three-cylinder three-crank engine. The cylinder ratios, he claims, should be designed so as to obtain equal initial loads in each cylinder. The ratios determined for the triple engine are 1, 2.04, 6.54, and for the quadruple, 1, 2.08, 4.46, 10.47. He advocates long stroke, high piston-speed, 100 revolutions per minute, and 250 lbs. boiler-pressure, unjacketed cylinders, and separate steam and exhaust valves.

**Diameters of Cylinders of Recent Triple-expansion Engines, Chiefly Marine.**

Compiled from several sources, 1890-1893.

Diam. in inches: *H* = high pressure, *I* = intermediate, *L* = low pressure.

Where the figures are bracketed there are two cylinders of a kind. Two 28" = one 39.6", two 31" = one 43.8", two 32.5" = one 46.0", two 36" = one 50.9", two 37" = one 52.3", two 40" = one 56.6", two 81.5" = one 115", two 85.7" = one 121", two 98" = one 140". The average ratio of diameters of cylinders of all the engines in the above table is nearly 1 to 1.60 to 2.56 and the ratio of areas nearly 1 to 2.56 to 6.55.

**The Progress in Steam-engines** between 1876 and 1893 is shown in the following comparison of the Corliss engine at the Centennial Exhibition in 1876 and the Allis-Corliss quadruple-expansion engine at the Chicago Exhibition.

Engine.....	1893. { Quadruple- expansion. }	1876. Simple
Cylinders, number.....	4	2
"    diameter.....	24, 40, 60, 70 in.	40 in.
"    stroke.....	72 in.	120 in.
Fly-wheel, diameter.....	30 ft.	30 ft.
"    width of face.....	76 in.	24 in.
"    weight.....	136,000 lbs.	125,440 lbs.
Revolutions per minute.....	60	36
Capacity, economical.....	2000 H.P.	1400 H.P.
"    maximum.....	3000 H.P.	2500 H.P.
Total weight.....	650,000 lbs.	1,360,588 lbs.

The crank-shaft body or wheel-seat of the Allis engine has a diameter of 21 inches, journals 19 inches, and crank bearings 18 inches, with a total length of 18 feet. The crank-disks are of cast iron and are 8 feet in diameter. The crank-pins are 9 inches in diameter by 9 inches long.

**A Double-tandem Triple-expansion Engine**, built by Watts, Campbell & Co., Newark, N. J., is described in *Am. Mach.*, April 26, 1894. It is two three-cylinder tandem engines coupled to one shaft, cranks at 90°, cylinders 21, 32 and 48 by 60 in. stroke, 65 revolutions per minute, rated H.P. 2000; fly-wheel 28 feet diameter, 12 ft. face, weight 174,000 lbs.; main shaft 22 in. diameter at the swell; main journals 19 x 38 in.; crank-pins 9½ x 10 in.; distance between centre lines of two engines 24 ft. 7½ in.; Corliss valves, with separate eccentrics for the exhaust-valves of the l.p. cylinder.

**Feed-water Consumption of Different Types of Engines.**

—The following tables are taken from the circular of the *Tabor Indicator* (Ashcroft Mfg. Co., 1889). In the first of the two columns under Feed-water required, in the tables for simple engines, the figures are obtained by computation from nearly perfect indicator diagrams, with allowance for cylinder condensation according to the table on page 752, but without allowance for leakage, with back-pressure in the non-condensing table taken at 16 lbs. above zero, and in the condensing table at 3 lbs. above zero. The compression curve is supposed to be hyperbolic, and commences at 0.91 of the return-stroke, with a clearance of  $\frac{3}{8}$  of the piston-displacement.

Table No. 2 gives the feed-water consumption for jacketed compound-con-

densing engines of the best class. The water condensed in the jackets is included in the quantities given. The ratio of areas of the two cylinders are as 1 to 4 for 120 lbs. pressure; the clearance of each cylinder is 3%; and the cut off in the two cylinders occurs at the same point of stroke. The initial pressure in the l. p. cylinder is 1 lb. per sq. in. below the back-pressure of the h. p. cylinder. The average back pressure of the whole stroke in the l. p. cylinder is 4.5 lbs. for 10% cut-off; 4.75 lbs. for 20% cut-off; and 5 lbs. for 30% cut-off. The steam accounted for by the indicator at cut-off in the h. p. cylinder (allowing a small amount for leakage) is .74 at 10% cut-off, .78 at 20%, and .82 at 30% cut-off. The loss by condensation between the cylinders is such that the steam accounted for at cut-off in the l. p. cylinder, expressed in proportion of that shown at release in the h. p. cylinder, is .85 at 10% cut-off, .87 at 20% cut-off, and .89 at 30% cut-off.

The data upon which table No. 3 is calculated are not given, but the feed-water consumption is somewhat lower than has yet been reached (1894), the lowest steam consumption of a triple-exp. engine yet recorded being 11.7 lbs.

**Most Economical Point of Cut-off in Steam-engines.**

(See paper by Wolff and Denton, Trans. A. S. M. E., vol. ii. p. 147-281; also, Ratio of Expansion at Maximum Efficiency, R. H. Thurston, vol. ii. p. 128.)  
 —The problem of the best ratio of expansion is not one of economy of consumption of fuel and economy of cost of boiler alone. The question of interest on cost of engine, depreciation of value of engine, repairs of engine, etc., enters as well; for as we increase the rate of expansion, and thus, within certain limits fixed by the back-pressure and condensation of steam, decrease the amount of fuel required and cost of boiler per unit of work, we have to increase the dimensions of the cylinder and the size of the engine, to attain the required power. We thus increase the cost of the engine, etc., as we increase the rate of expansion, while at the same time we decrease the fuel consumption, the cost of boiler, etc. So that there is in every engine some point of cut-off, determinable by calculation and graphical construction, which will secure the greatest efficiency for a given expenditure of money, taking into consideration the cost of fuel, wages of engineer and firemen, interest on cost, depreciation of value, repairs to and insurance of boiler and engine, and oil, waste, etc., used for engine. In case of freight-carrying vessels, the value of the room occupied by fuel should be considered in estimating the cost of fuel.

**Sizes and Calculated Performances of Vertical High-speed Engines.**—The following tables are taken from a circular of the Field Engineering Co., New York, describing the engines made by the Lake Erie Engineering Works, Buffalo, N. Y. The engines are fair representatives of the type now coming largely into use for driving dynamos directly without belts. The tables were calculated by E. F. Williams, designer of the engines. They are here somewhat abridged to save space:

**Simple Engines—Non-condensing.**

**Type of Engine to be used where Exhaust-steam is needed for Heating.**—In many factories more or less of the steam exhausted from the engines is utilized for boiling, drying, heating, etc. Where all the exhaust-steam is so used the question of economical use of steam in the engine itself is eliminated, and the high-pressure simple engine is entirely suitable. Where only part of the exhaust-steam is used, and the quantity so used varies at different times, the question of adopting a simple, a condensing, or a compound engine becomes more complex. This problem is treated by C. T. Main in *Trans. A. S. M. E.*, vol. x. p. 48. He shows that the ratios of the volumes of the cylinders in compound engines should vary according to the amount of exhaust-steam that can be used for heating. A case is given in which three different pressures of steam are required or could be used, as in a worsted dye-house: the high or boiler pressure for the engine, an intermediate pressure for crabbing, and low-pressure for boiling, drying, etc. If it did not make too much complication of parts in the engine, the boiler-pressure might be used in the high-pressure cylinder, exhausting into a receiver from which steam could be taken for running small engines and crabbing, the steam remaining in the receiver passing into the intermediate cylinder and expanded there to from 5 to 10 lbs. above the atmosphere and exhausted into a second receiver. From this receiver is drawn the low-pressure steam needed for drying, boiling, warming mills, etc., the steam remaining in receiver passing into the condensing cylinder.

#### Comparison of the Economy of Compound and Single-cylinder Corliss Condensing Engines, each expanding about Sixteen Times. (D. S. Jacobus, *Trans. A. S. M. E.*, xii. 943.)

The engines used in obtaining comparative results are located at Stations I. and II. of the Pawtucket Water Co.

The tests show that the compound engine is about 30% more economical than the single-cylinder engine. The dimensions of the two engines are as follows: Single 20"  $\times$  48"; compound 15" and 30 $\frac{1}{8}$ "  $\times$  30". The steam used per horse-power per hour was: single 20.35 lbs., compound 13.73 lbs.

Both of the engines are steam-jacketed, practically on the barrels only, with steam at full boiler-pressure, viz. single 106.3 lbs., compound 127.5 lbs.

2. A triple 500 horse-power plant costs \$20,500, and saves about \$114 per year in 10-hour service, or \$826 in 24-hour service, over a compound plant, thereby saving its extra cost in 10-hour service in about 19¾ years, or in 24-hour service in about 2¾ years.

\* These figures do not include the heat saved by the economizer; including this they are 163,912,300; 187.8; 22.58. The Nordberg engine had a series of feed-water heaters taking steam respectively from the exhaust, from the low-pressure cylinder, and from the third, second, and first receivers. The feed-water was thereby treated successively to 105°, 136°, 193°, 260°, and 311° F. The coal consumption of the Chestnut Hill engine was 1.062 lbs. per I.H.P. per hour, including the coal used by the fan, stoker, and economizer engines. This is the lowest figure yet recorded.

### Steam Consumption of Sulzer Compound and Triple-expansion Engines with Superheated Steam.

The figures on the next page were furnished to the author (Aug., 1902) by Sulzer Bros., Winterthur, Switzerland. They are the results of official tests by Prof. Schröter of Munich, Prof. Weber of Zurich, and other eminent engineers.

**Relative Economy of Compound Non-condensing Engines under Variable Loads.**—F. M. Rites, in a paper on the Steam Distribution in a Form of Single-acting Engine (Trans. A. S. M. E., xiii. 537), discusses an engine designed to meet the following problem: Given an extreme range of conditions as to load or steam-pressure, either or both, to fluctuate together or apart, violently or with easy gradations, to construct an engine whose economical performance should be as good as though the engine were specially designed for a momentary condition—the adjustment to be complete and automatic. In the ordinary non-condensing compound engine with light loads the high-pressure cylinder is frequently forced to supply all the power and in addition drag along with it the low-pressure piston, whose cylinder indicates negative work. Mr. Rites shows the peculiar value of a receiver of predetermined volume which acts as a clearance chamber for compression in the high-pressure cylinder. The Westinghouse compound single-acting engine is designed upon this principle. The following results of tests of one of these engines rated at 175 H.P. for most economical load are given:

WATER RATES UNDER VARYING LOADS, LBS. PER H.P. PER HOUR.

Horse-power.....	210	170	140	115	100	80	50
Non-condensing.....	22.6	21.9	22.2	22.2	22.4	24.6	28.8
Condensing .....	18.4	18.1	18.2	18.2	18.3	18.3	20.4

**Efficiency of Non-condensing Compound Engines.** (W. Lee Church, *Am. Mach.*, Nov. 19, 1891.)—The compound engine, non-condensing, at its best performance will exhaust from the low-pressure cylinder at a pressure 2 to 6 pounds above atmosphere. Such an engine will be limited in its economy to a very short range of power, for the reason that its valve-motion will not permit of any great increase beyond its rated power, and any material decrease below its rated power at once brings the expansion curve in the low-pressure cylinder below atmosphere. In other words, decrease of load tells upon the compound engine somewhat sooner, and much more severely, than upon the non-compound engine. The loss commences the moment the expansion line crosses a line parallel to the atmospheric line, and at a distance above it representing the mean effective pressure necessary to carry the frictional load of the engine. When expansion falls to this point the low-pressure cylinder becomes an air-pump over more or less of its stroke, the power to drive which must come from the high pressure cylinder alone. Under the light loads common in many industries the low-pressure cylinder is thus a positive resistance for the greater portion of its stroke. A careful study of this problem revealed the functions of a fixed intermediate clearance, always in communication with the high-pressure cylinder, and having a volume bearing the same ratio to that of the high-pressure cylinder that the high-pressure cylinder bears to the low-pressure. Engines laid down on these lines have fully confirmed the judgment of the designers.

The effect of this constant clearance is to supply sufficient steam to the low-pressure cylinder under light loads to hold its expansion curve up to atmosphere, and at the same time leave a sufficient clearance volume in the high-pressure cylinder to permit of governing the engine on its compression under light loads.

**Economy of Engines under Varying Loads.** (From Prof. W. C. Unwin's lecture before the Society of Arts, London, 1892.)—The general result of numerous trials with large engines was that with a constant load an indicated horse-power should be obtained with a consumption of  $1\frac{1}{2}$  pounds of coal per indicated horse-power for a condensing engine, and  $1\frac{3}{4}$  pounds for a non-condensing engine, figures which correspond to about  $1\frac{3}{4}$  pounds to  $2\frac{1}{8}$  pounds of coal per effective horse-power. It was much more difficult to ascertain the consumption of coal in ordinary every-day work, but such facts as were known showed it was more than on trial.

In electric-lighting stations the engines work under a very fluctuating load, and the results are far more unfavorable. An excellent Willans non-condensing engine, which on full-load trials worked with under 2 pounds per effective horse-power hour, in the ordinary daily working of the station used  $7\frac{1}{2}$  pounds per effective H.P. hour in 1886, which was reduced to 4.3 pounds in 1890 and 3.8 pounds in 1891. Probably in very few cases were the engines at electric-light stations working under a consumption of  $4\frac{1}{2}$  pounds per effective H.P. hour. In the case of small isolated motors working with a fluctuating load, still more extravagant results were obtained.

ENGINES IN ELECTRIC CENTRAL STATIONS.

Year.....	1886.	1890.	1892.
Coal used per hour per effective H.P.....	8.4	5.6	4.9
“ “ “ “ “ indicated “ .....	6.5	4.35	3.8

At electric-lighting stations the load factor, viz., the ratio of the average load to the maximum, is extremely small, and the engines worked under very unfavorable conditions, which largely accounted for the excessive fuel consumption at these stations.

In steam-engines the fuel consumption has generally been reckoned on the indicated horse-power. At full-power trials this was satisfactory enough, as the internal friction is then usually a small fraction of the total.

Experiment has, however, shown that the internal friction is nearly constant, and hence, when the engine is lightly loaded, its mechanical efficiency is greatly reduced. At full load small engines have a mechanical efficiency of 0.8 to 0.85, and large engines might reach at least 0.9, but if the internal friction remained constant this efficiency would be much reduced at low powers. Thus, if an engine working at 100 indicated horse-power had an efficiency of 0.85, then when the indicated horse-power fell to 50 the effective horse-power would be 35 horse-power and the efficiency only 0.7. Similarly, at 25 horse-power the effective horse-power would be 10 and the efficiency 0.4.

Experiments on a Corliss engine at Creusot gave the following results :

Effective power at full load . . . . .	1.0	0.75	0.50	0.25	0.125
Condensing, mechanical efficiency.....	0.82	0.79	0.74	0.63	0.48
Non condensing, “ “ .....	0.86	0.83	0.78	0.67	0.52

At light loads the economy of gas and liquid fuel engines fell off even more rapidly than in steam-engines. The engine friction was large and nearly constant, and in some cases the combustion was also less perfect at light loads. At the Dresden Central Station the gas-engines were kept working at nearly their full power by the use of storage-batteries. The results of some experiments are given below :

Brake-load, per cent of full Power.	Gas-engine, cu. ft. of Gas per Brake H.P. per hour.	Petroleum Eng., Lbs. of Oil per B.H.P. per hr.	Petroleum Eng., Lbs. of Oil per B.H.P. per hr.
100	22.2	0.96	0.88
75	23.8	1.11	0.99
59	28.0	1.44	1.20
20	40.8	2.38	1.82
12½	66.3	4.25	3.07

**Steam Consumption of Engines of Various Sizes.**—W. C. Unwin (*Cassier's Magazine*, 1894) gives a table showing results of 49 tests of engines of different types. In non-condensing simple engines, the steam consumption ranged from 65 lbs. per hour in a 5-horse-power engine to 22 lbs. in a 134-H.P. Harris-Corliss engine. In non-condensing compound engines, the only type tested was the Willans, which ranged from 27 lbs. in a 10 H.P. slow-speed engine, 120 ft. per minute, with steam-pressure of 84 lbs. to 19.2 lbs. in a 40-H.P. engine, 401 ft. per minute, with steam-pressure 165 lbs. A Willans triple-expansion non-condensing engine, 39 H.P., 172 lbs. pressure, and 400 ft. piston speed per minute, gave a consumption of 18.5 lbs. In condensing engines, nine tests of simple engines gave results ranging only from 18.4 to 22 lbs., and, leaving out a beam pumping-engine running at slow speed (240 ft. per minute) and low steam-pressure (45 lbs.), the range is only from 18.4 to 19.8 lbs. In compound-condensing engines over 100 H.P., in 13 tests the range is from 13.9 to 20 lbs. In three triple-expansion engines the figures are 11.7, 12.2, and 12.45 lbs., the lowest being a Sulzer engine of 360 H.P. In marine compound engines, the Fusiyama and Colchester, tested by Prof. Kennedy, gave steam consumption of 21.2 and 21.7 lbs.; and the Meteor and Tartar triple-expansion engines gave 15.0 and 19.8 lbs.

Taking the most favorable results which can be regarded as not exceptional, it appears that in test trials, with constant and full load, the expenditure of steam and coal is about as follows:

Kind of Engine.	Per Indicated Horse-power Hour.		Per Effective Horse-power Hour.	
	Coal, lbs.	Steam, lbs.	Coal, lbs.	Steam, lbs.
Non-condensing.....	1.80	16.5	2.00	18.0
Condensing.....	1.50	13.5	1.75	15.8

These may be regarded as minimum values, rarely surpassed by the most efficient machinery, and only reached with very good machinery in the favorable conditions of a test trial.

**Small Engines and Engines with Fluctuating Loads** are usually very wasteful of fuel. The following figures, illustrating their low economy, are given by Prof. Unwin, Cassier's *Magazine*, 1894.

COAL CONSUMPTION PER INDICATED HORSE-POWER IN SMALL ENGINES.

In Workshops in Birmingham, Eng.

Probable I.H.P. at full load...	12	45	60	45	75	60	60
Average I.H.P. during observation..	2.96	7.37	8.2	8.6	23.64	19.08	20.08
Coal per I.H.P. per hour during observation, lbs.....	36.0	21.25	22.61	18.13	11.68	9.53	8.50

It is largely to replace such engines as the above that power will be distributed from central stations.

**Steam Consumption in Small Engines.**

THROTTLING-ENGINE, 7/8 CUT-OFF, FOR CORRESPONDING HORSE-POWERS.

Boiler-pressure, 90 lbs...	42	37	33.8	31.5	29.8	....	....	....	....
" " 60 lbs...	....	50.1	49	46.8	44.6	41	....	....	....

Some of the principal conclusions from this series of tests are as follows :

1. There is a distinct gain in economy of steam as the speed increases for 1/2, 1/8, and 1/4 cut-off at 90 lbs. pressure. The loss in economy for about 1/4 cut-off is at the rate of 1/12 lb. of water per H.P. for each decrease of a revolution per minute from 86 to 26 revolutions, and at the rate of 5/8 lb. of water below 26 revolutions. Also, at all speeds the 1/4 cut-off is more economical than either the 1/2 or 1/8 cut-off.

2. At 90 lbs. boiler-pressure and above 1/3 cut-off, to produce a given H.P. requires about 20% less steam than to cut off at 7/8 stroke and regulate by the throttle.

3. For the same conditions with 60 lbs. boiler-pressure, to obtain, by throttling, the same mean effective pressure at 7/8 cut-off that is obtained by

cutting off about  $\frac{1}{3}$ , requires about 30% more steam than for the latter condition.

**High Piston-speed in Engines.** (Proc. Inst. M. E., July, 1883, p. 321).—The torpedo boat is an excellent example of the advance towards high speeds, and shows what can be accomplished by studying lightness and strength in combination. In running at  $22\frac{1}{2}$  knots an hour, an engine with cylinders of 16 in. stroke will make 480 revolutions per minute, which gives 1280 ft. per minute for piston-speed; and it is remarked that engines running at that high rate work much more smoothly than at lower speeds, and that the difficulty of lubrication diminishes as the speed increases.

**A High-speed Corliss Engine.**—A Corliss engine,  $20 \times 42$  in., has been running a wire-rod mill at the Trenton Iron Co.'s works since 1877, at 160 revolutions or 1120 ft. piston-speed per minute (Trans. A. S. M. E., ii. 72). A piston-speed of 1200 ft. per min. has been realized in locomotive practice.

**The Limitation of Engine-speed.** (Chas. T. Porter, in a paper on the Limitation of Engine-speed, Trans. A. S. M. E., xiv. 806.)—The practical limitation to high rotative speed in stationary reciprocating steam-engines is not found in the danger of heating or of excessive wear, nor, as is generally believed, in the centrifugal force of the fly-wheel, nor in the tendency to knock in the centres, nor in vibration. He gives two objections to very high speeds: First, that "engines ought not to be run as fast as they can be;" second, the large amount of waste room in the port, which is required for proper steam distribution. In the important respect of economy of steam, the high-speed engine has thus far proved a failure. Large gain was looked for from high speed, because the loss by condensation on a given surface would be divided into a greater weight of steam, but this expectation has not been realized. For this unsatisfactory result we have to lay the blame chiefly on the excessive amount of waste room. The ordinary method of expressing the amount of waste room in the percentage added by it to the total piston displacement, is a misleading one. It should be expressed as the percentage which it adds to the length of steam admission. For example, if the steam is cut off at  $\frac{1}{5}$  of the stroke, 8% added by the waste room to the total piston displacement means 40% added to the volume of steam admitted. Engines of four, five and six feet stroke may properly be run at from 700 to 800 ft. of piston travel per minute, but for ordinary sizes, says Mr. Porter, 600 ft. per minute should be the limit.

**Influence of the Steam-jacket.**—Tests of numerous engines with and without steam-jackets show an exceeding diversity of results, ranging all the way from 30% saving down to zero, or even in some cases showing an actual loss. The opinions of engineers at this date (1894) is also as diverse as the results, but there is a tendency towards a general belief that the jacket is not as valuable an appendage to an engine as was formerly supposed. An extensive *résumé* of facts and opinions on the steam-jacket is given by Prof. Thurston, in Trans. A. S. M. E., xiv. 462. See also Trans. A. S. M. E., xiv. 873 and 1340; xiii. 176; xii. 426 and 1340; and Jour. F. I., April, 1891, p. 276. The following are a few statements selected from these papers.

The results of tests reported by the research committee on steam-jackets appointed by the British Institution of Mechanical Engineers in 1886, indicate an increased efficiency due to the use of the steam-jacket of from 1% to over 30%, according to varying circumstances.

Sennett asserts that "it has been abundantly proved that steam-jackets are not only advisable but absolutely necessary, in order that high rates of expansion may be efficiently carried out and the greatest possible economy of heat attained."

Isherwood finds the gain by its use, under the conditions of ordinary practice, as a general average, to be about 20% on small and 8% or 9% on large engines, varying through intermediate values with intermediate sizes, it being understood that the jacket has an effective circulation, and that both heads and sides are jacketed.

Professor Unwin considers that "in all cases and on all cylinders the jacket is useful; provided, of course, ordinary, not superheated, steam is used; but the advantages may diminish to an amount not worth the interest on extra cost."

Professor Cotterill says: Experience shows that a steam-jacket is advantageous, but the amount to be gained will vary according to circumstances. In many cases it may be that the advantage is small. Great caution is necessary in drawing conclusions from any special set of experiments on the influence of jacketing.

Mr. E. D. Leavitt has expressed the opinion that, in his practice, steam-jackets produce an increase of efficiency of from 15% to 20%.

In the Pawtucket pumping engine, 15 and  $30\frac{1}{8} \times 30$  in., 50 revs. per min., steam-pressure 125 lbs. gauge, cut-off  $\frac{1}{4}$  in h.p. and  $\frac{1}{3}$  in l.p. cylinder, the barrels only jacketed, the saving by the jackets was from 1% to 4%.

The superintendent of the Holly Mfg. Co. (compound pumping-engines) says: "In regard to the benefits derived from steam-jackets on our steam-cylinders, I am somewhat of a skeptic. From data taken on our own engines and tests made I am yet to be convinced that there is any practical value in the steam-jacket." . . . "You might practically say that there is no difference."

Professor Schröter from his work on the triple-expansion engines at Augsburg, and from the results of his tests of the jacket efficiency on a small engine of the Sulzer type in his own laboratory, concludes: (1) The value of the jacket may vary within very wide limits, or even become negative. (2) The shorter the cut-off the greater the gain by the use of a jacket. (3) The use of higher pressure in the jacket than in the cylinder produces an advantage. The greater this difference the better. (4) The high-pressure cylinder may be left unjacketed without great loss, but the others should always be jacketed.

The test of the Laketon triple-expansion pumping-engine showed a gain of 8.3% by the use of the jackets, but Prof. Denton points out (Trans. A. S. M. E., xiv. 1412) that all but 1.9% of the gain was ascribable to the greater range of expansion used with the jackets.

**Test of a Compound Condensing Engine with and without Jackets at different Loads.** (R. C. Carpenter, Trans. A. S. M. E., xiv. 428.)—Cylinders 9 and 16 in.  $\times$  14 in. stroke; 112 lbs. boiler-pressure; rated capacity 100 H.P.; 265 revs. per min. Vacuum, 23 in. From the results of several tests curves are plotted, from which the following principal figures are taken.

Indicated H.P. ....	30	40	50	60	70	80	90	100	110	120	125
Steam per I.H.P. per hour:											
With jackets, lbs. . . . .	22.6	21.4	20.3	19.6	19	18.7	18.6	18.9	19.5	20.4	21.0
Without jackets, lbs. . . . .	....	....	....	22.	20.5	19.6	19.2	19.1	19.3	20.1	....
Saving by jacket, p. c. ....	....	....	....	10.9	7.3	4.6	3.1	1.0	-1.0	-1.5	....

This table gives a clue to the great variation in the apparent saving due to the steam-jacket as reported by different experimenters. With this particular engine it appears that when running at its most economical rate of 100 H.P., without jackets, very little saving is made by use of the jackets. When running light the jacket makes a considerable saving, but when overloaded it is a detriment.

At the load which corresponds to the most economical rate, with no steam in jackets, or 100 H.P., the use of the jacket makes a saving of only 1%; but at a load of 60 H.P. the saving by use of the jacket is about 11%, and the shape of the curve indicates that the relative advantage of the jacket would be still greater at lighter loads than 60 H.P.

**Counterbalancing Engines.**—Prof. Unwin gives the formula for counterbalancing vertical engines:

$$W_1 = W_2 \frac{r}{p}; \dots \dots \dots (1)$$

in which  $W_1$  denotes the weight of the balance weight and  $p$  the radius to its centre of gravity,  $W_2$  the weight of the crank-pin and half the weight of the connecting-rod, and  $r$  the length of the crank. For horizontal engines:

$$W_1 = \frac{2}{3}(W_2 + W_3) \frac{r}{p} \text{ to } \frac{3}{4}(W_2 + W_3) \frac{r}{p}, \dots \dots \dots (2)$$

in which  $W_3$  denotes the weight of the piston, piston-rod, cross-head, and the other half of the weight of the connecting-rod.

The *American Machinist*, commenting on these formulæ, says: For horizontal engines formula (2) is often used; formula (1) will give a counterbalance too light for vertical engines. We should use formula (2) for computing the counterbalance for both horizontal and vertical engines, excepting locomotives, in which the counterbalance should be heavier.

**Preventing Vibrations of Engines.**—Many suggestions have been made for remedying the vibration and noise attendant on the working of the big engines which are employed to run dynamos. A plan which has given great satisfaction is to build hair-felt into the foundations of the engine. An electric company has had a 90-horse-power engine removed from its foundations, which were then taken up to the depth of 4 feet. A layer of felt 5 inches thick was then placed on the foundations and run up 2 feet on all sides, and on the top of this the brickwork was built up.—*Safety Valve.*

**Steam-engine Foundations Embedded in Air.**—In the sugar-refinery of Claus Spreckels, at Philadelphia, Pa., the engines are distributed practically all over the buildings, a large proportion of them being on upper floors. Some are bolted to iron beams or girders, and are consequently innocent of all foundation. Some of these engines ran noiselessly and satisfactorily, while others produced more or less vibration and rattle. To correct the latter the engineers suspended foundations from the bottoms of the engines, so that, in looking at them from the lower floors, they were literally hanging in the air.—*Iron Age.* Mar. 13, 1890.

**Cost of Coal for Steam-power.**—The following table shows the amount and the cost of coal per day and per year for various horse-powers, from 1 to 1000, based on the assumption of 4 lbs. of coal being used per hour per horse-power. It is useful, among other things, in estimating the saving that may be made in fuel by substituting more economical boilers and engines for those already in use. Thus with coal at \$3.00 per ton, a saving of \$9000 per year in fuel may be made by replacing a steam plant of 1000 H.P., requiring 4 lbs. of coal per hour per horse-power, with one requiring only 2 lbs.

Horse-power.	Coal Consumption, at 4 lbs. per H.P. per hour; 10 hours a day; 300 days in a Year.					\$1.50.		\$2.00.		\$3.00.		\$4.00.

**Storing Steam Heat.**—There is no satisfactory method for equalizing the load on the engines and boilers in electric-light stations. Storage-batteries have been used, but they are expensive in first cost, repairs, and attention. Mr. Halpin, of London, proposes to store heat during the day in specially constructed reservoirs. As the water in the boilers is raised to 250 lbs. pressure, it is conducted to cylindrical reservoirs resembling English horizontal boilers, and stored there for use when wanted. In this way a comparatively small boiler-plant can be used for heating the water to 250 lbs. pressure all through the twenty-four hours of the day, and the stored water may be drawn on at any time, according to the magnitude of the demand. The

steam-engines are to be worked by the steam generated by the release of pressure from this water, and the valves are to be arranged in such a way that the steam shall work at 130 lbs. pressure. A reservoir 8 ft. in diameter and 30 ft. long, containing 84,000 lbs. of heated water at 250 lbs. pressure, would supply 5250 lbs. of steam at 130 lbs. pressure. As the steam consumption of a condensing electric-light engine is about 18 lbs. per horse-power hour, such a reservoir would supply 286 effective horse-power hours. In 1878, in France, this method of storing steam was used on a tramway. M. Francq, the engineer, designed a smokeless locomotive to work by steam-power supplied by a reservoir containing 400 gallons of water at 220 lbs. pressure. The reservoir was charged with steam from a stationary boiler at one end of the tramway.

**Cost of Steam-power.** (Chas. T. Main, A. S. M. E., x. 48.)—Estimated costs in New England in 1888, per horse-power, based on engines of 1000 H.P.

	Compound Engine.	Condensing Engine.	Non-condensing Engine.

28. Total yearly expense, lines 10, 20, and 27..	24.087	29.355	33.248
29. Total yearly expense per I.H.P. for power if 50% of exhaust-steam is used for heating .....	12.597	14.907	16.663
30. Total if all ex.-steam is used for heating...	8.624	7.916	7.700

When exhaust-steam or a part of the receiver-steam is used for heating, or if part of the steam in a condensing engine is diverted from the condenser, and used for other purposes than power, the value of such steam should be deducted from the cost of the total amount of steam generated in order to arrive at the cost properly chargeable to power. The figures in lines 29

and 30 are based on an assumption made by Mr. Main of losses of heat amounting to 25% between the boiler and the exhaust-pipe, an allowance which is probably too large.

See also two papers by Chas. E. Emery on "Cost of Steam Power," Trans. A. S. C. E., vol. xii, Nov. 1883, and Trans. A. I. E. E., vol. x, Mar. 1893.

### ROTARY STEAM-ENGINES.

**Steam Turbines.**—The steam turbine is a small turbine wheel which runs with steam as the ordinary turbine does with water. (For description of the Parsons and the Dow steam turbines see *Modern Mechanism*, p. 298, etc.) The Parsons turbine is a series of parallel-flow turbines mounted side by side on a shaft; the Dow turbine is a series of radial outward-flow turbines, placed like a series of concentric rings in a single plane, a stationary guide-ring being between each pair of movable rings. The speeds of the steam turbines enormously exceed those of any form of engine with reciprocating piston, or even of the so-called rotary engines. The three- and four-cylinder engines of the Brotherhood type, in which the several cylinders are usually grouped radially about a common crank and shaft, often exceed 1000 revolutions per minute, and have been driven, experimentally, above 2000; but the steam turbine of Parsons makes 10,000 and even 20,000 revolutions, and the Dow turbine is reputed to have attained 25,000. (See Trans. A. S. M. E., vol. x, p. 680, and xii, p. 888; Trans. Assoc. of Eng'g Societies, vol. viii, p. 583; *Eng'g*, Jan. 13, 1888, and Jan. 8, 1892; *Eng'g News*, Feb. 27, 1892.) A Dow turbine, exhibited in 1889, weighed 68 lbs., and developed 10 H.P., with a consumption of 47 lbs. of steam per H.P. per hour, the steam pressure being 70 lbs. The Dow turbine is used to spin the fly-wheel of the Howell torpedo. The dimensions of the wheel are 13.8 in. diam., 6.5 in. width, radius of gyration 5.57 in. The energy stored in it at 10,000 revs. per min. is 500,000 ft.-lbs.

The *De Laval Steam Turbine*, shown at the Chicago exhibition, 1893, is a reaction wheel somewhat similar to the Pelton water-wheel. The steam jet is directed by a nozzle against the plane of the turbine at quite a small angle and tangentially against the circumference of the medium periphery of the blades. The angle of the blades is the same at the side of admission and discharge. The width of the blade is constant along the entire thickness of the turbine.

The steam is expanded to the pressure of the surroundings before arriving at the blades. This expansion takes place in the nozzle, and is caused simply by making its sides diverging. As the steam passes through this channel its specific volume is increased in a greater proportion than the cross section of the channel, and for this reason its velocity is increased, and also its momentum, till the end of the expansion at the last sectional area of the nozzle. The greater the expansion in the nozzle the greater its velocity at this point. A pressure of 75 lbs. and expansion to an absolute pressure of one atmosphere give a final velocity of about 2625 ft. per second.

Expansion is carried further in this steam turbine than in ordinary steam-engines. This is on account of the steam expanding completely during its work to the pressure of the surroundings.

For obtaining the greatest possible effect the admission to the blades must be free from blows and the velocity of discharge as low as possible. These conditions would require in the steam turbine an enormous velocity of periphery—as high as 1300 to 1650 ft. per second. The centrifugal force, nevertheless, puts a limit to the use of very high velocities. In the 5 horse-power turbine the velocity of periphery is 574 ft. per second, and the number of revolutions 30,000 per minute.

However carefully the turbine may be manufactured it is impossible, on account of unevenness of the material, to get its centre of gravity to correspond exactly to its geometrical axle of revolution; and however small this difference may be, it becomes very noticeable at such high velocities. De Laval has succeeded in solving the problem by providing the turbine with a flexible shaft. This yielding shaft allows the turbine at the high rate of speed to adjust itself and revolve around its true centre of gravity, the centre line of the shaft meanwhile describing a surface of revolution.

In the gearing-box the speed is reduced from 30,000 revolutions to 3000 by means of a driver on the turbine shafts, which sets in motion a cog-wheel of 10 times its own diameter. These gearings are provided with spiral cogs placed at an angle of about 45°.

For descriptions of the most recent forms of steam turbines, see circulars of the Westinghouse Machine Co., Pittsburg, Pa., and the De Laval Steam

Turbine Co., Trenton, N. J.; also paper by Dr. R. H. Thurston in Trans. A. S. M. E., vol. xxii., p. 170.

**Rotary Steam-engines**, other than steam turbines, have been invented by the thousands, but not one has attained a commercial success, as regards economy of steam. The possible advantages, such as saving of space, to be gained by a rotary engine are overbalanced by its waste of steam. Rotary engines are in use, however, for special purposes, such as steam fire-engines and steam feeds for sawmills, in which steam economy is not a matter of importance.

**DIMENSIONS OF PARTS OF ENGINES.**

The treatment of this subject by the leading authorities on the steam-engine is very unsatisfactory, being a confused mass of rules and formulæ based partly upon theory and partly upon practice. The practice of builders shows an exceeding diversity of opinion as to correct dimensions. The treatment given below is chiefly the result of a study of the works of Rankine, Seaton, Unwin, Thurston, Marks, and Whitham, and is largely a condensation of a series of articles by the author published in the *American Machinist*, in 1894, with many alterations and much additional matter. In order to make a comparison of many of the formulæ they have been applied to the assumed cases of six engines of different sizes, and in some cases this comparison has led to the construction of new formulæ.

**Cylinder.** (Whitham.)—Length of bore = stroke + breadth of piston-ring - 1/8 to 1/2 in.; length between heads = stroke + thickness of piston + sum of clearances at both ends; thickness of piston = breadth of ring + thickness of flange on one side to carry the ring + thickness of follower-plate.

Thickness of flange or follower....	3/8 to 1/2 in.	3/4 in.	1 in.
For cylinder of diameter.....	8 to 10 in.	36 in.	60 to 100 in.

**Clearance of Piston.** (Seaton.)—The clearance allowed varies with the size of the engine from 1/8 to 3/8 in. for roughness of castings and 1/16 to 1/8 in. for each working joint. Naval and other very fast-running engines have a larger allowance. In a vertical direct-acting engine the parts which wear so as to bring the piston nearer the bottom are three, viz., the shaft journals, the crank-pin brasses, and piston-rod gudgeon-brasses.

**Thickness of Cylinder.** (Thurston.)—For engines of the older types and under moderate steam-pressures, some builders have for many years restricted the stress to about 2550 lbs. per sq. in.

$$t = ap_1D + b \dots \dots \dots (1)$$

is a common proportion; *t*, *D*, and *b* being thickness, diam., and a constant added quantity varying from 0 to 1/2 in., all in inches; *p*<sub>1</sub> is the initial unbalanced steam-pressure per sq. in. In this expression *b* is made larger for horizontal than for vertical cylinders, as, for example, in large engines 0.5 in the one case and 0.2 in the other, the one requiring re-boring more than the other. The constant *a* is from 0.0004 to 0.0005; the first value for vertical cylinders, or short strokes; the second for horizontal engines, or for long strokes.

**Thickness of Cylinder and its Connections for Marine Engines.** (Seaton.)—*D* = the diam. of the cylinder in inches; *p* = load on the safety-valves in lbs. per sq. in.; *f*, a constant multiplier = thickness of barrel + .25 in.

Thickness of metal of cylinder barrel or liner, not to be less than  $p \times D + 3000$  when of cast iron.\*

$$\text{Thickness of cylinder-barrel} = \frac{p \times D}{5000} + 0.6 \text{ in.} \dots \dots \dots (8)$$

$$\text{" " liner} = 1.1 \times f \dots \dots \dots (4)$$

Thickness of liner when of steel  $p \times D \div 6000 + 0.5$   
 " metal of steam-ports =  $0.6 \times f$ .  
 " " valve-box sides =  $0.65 \times f$ .

\* When made of exceedingly good material, at least twice melted, the thickness may be 0.8 of that given by the above rules.

Thickness of metal of valve-box covers	= 0.7	× <i>f</i> .
“ “ cylinder bottom	= 1.1	× <i>f</i> , if single thickness.
“ “ “ “	= 0.65	× <i>f</i> , if double “
“ “ “ covers	= 1.0	× <i>f</i> , if single “
“ “ “ “	= 0.6	× <i>f</i> , if double “
“ cylinder flange	= 1.4	× <i>f</i> .
“ “ cover-flange	= 1.3	× <i>f</i> .
“ “ valve-box “	= 1.0	× <i>f</i> .
“ “ door-flange	= 0.9	× <i>f</i> .
“ “ face over ports	= 1.2	× <i>f</i> .
“ “ “ “	= 1.0	× <i>f</i> , when there is a false-face.
“ “ false-face	= 0.8	× <i>f</i> , when cast iron.
“ “ “ “	= 0.6	× <i>f</i> , when steel or bronze.

Whitham gives the following from different authorities:

$$\text{Van Buren: } \begin{cases} t = 0.0001Dp + 0.15 \sqrt{D}; & \dots \dots \dots (5) \\ t = 0.03 \sqrt{Dp}. & \dots \dots \dots (6) \end{cases}$$

$$\text{Tredgold: } t = \frac{(D + 2.5)p}{1900}. \dots \dots \dots (7)$$

$$\text{Weisbach: } t = 0.8 + 0.00033pD. \dots \dots \dots (8)$$

$$\text{Seaton: } t = 0.5 + 0.0004pD. \dots \dots \dots (9)$$

$$\text{Haswell: } \begin{cases} t = 0.0004pD + \frac{1}{8} \text{ (vertical);} & \dots \dots \dots (10) \\ t = 0.0005pD + \frac{1}{8} \text{ (horizontal).} & \dots \dots \dots (11) \end{cases}$$

Whitham recommends (6) where provision is made for the reboring, and where ample strength and rigidity are secured, for horizontal or vertical cylinders of large or small diameter; (9) for large cylinders using steam under 100 lbs. gauge-pressure, and

$$t = 0.003D \sqrt{p} \text{ for small cylinders.} \dots \dots \dots (12)$$

$$\text{Marks gives } t = 0.00028pD. \dots \dots \dots (13)$$

This is a smaller value than is given by the other formulæ quoted; but Marks says that it is not advisable to make a steam-cylinder less than 0.75 in. thick under any circumstances.

The following table gives the calculated thickness of cylinders of engines of 10, 30, and 50 in. diam., assuming *p* the maximum unbalanced pressure on the piston = 100 lbs. per sq. in. As the same engines will be used for calculation of other dimensions, other particulars concerning them are here given for reference.

DIMENSIONS, ETC., OF ENGINES.

Engine No.....	1 and 2.		3 and 4.		5 and 6.	
Indicated horse-power.....I.H.P.	50		450		1250

Mean effective pressure ... M.E.P.	42		32.3		30	
Max. total unbalanced press..... <i>P</i>	7854		70,686		196,350	
Max. total per sq. in..... <i>p</i>	100		100		100	

THICKNESS OF CYLINDER BY FORMULA.	1 and 2.	3 and 4.	5 and 6.
(1) $.0004pD + 0.5$ , short stroke...	.90	1.70	2.50
(1) $.0005pD + 0.5$ , long stroke....	1.00	2.00	3.00
(2) $.00033pD$ .....	.33	.99	1.67
(3) $.0002pD + 0.6$ . . . . .	.80	1.40	1.66
(5) $.0001pD + .15 \sqrt{D}$ .....	.57	1.12	1.56
(6) $.03 \sqrt{Dp}$ .....	.95	1.64	2.12
(7) $\frac{(D + 2.5)}{1900} p$ .....	.66	1.71	2.76
(8) $.00033pD + 0.8$ .....	1.13	1.79	2.45
(9) $.0004pD + 0.5$ .....	.90	1.70	2.50
(10) $.0004pD + \frac{1}{8}$ (vertical).....	.53	1.33	2.13
(11) $.0005pD + \frac{1}{8}$ (horizontal).....	.63	1.63	2.63
(12) $.003D \sqrt{p}$ (small engines).....	.30(?)	....	....
(13) $.00028pD$ .....	.28(?)	.84(?)	1.40(?)
Average of first eleven. ....	.76	1.48	2.26

The average corresponds nearly to the formula  $t = .00037Dp + 0.4$  in. A convenient approximation is  $t = .0004Dp + 0.3$  in., which gives for

Diameters.....	10	20	30	40	50	60 in.
Thicknesses.....	.70	1.10	1.50	1.90	2.30	2.70 in.

The last formula corresponds to a tensile strength of cast iron of 12,500 lbs., with a factor of safety of 10 and an allowance of 0.3 in. for reboring.

**Cylinder-heads.**—Thurston says: Cylinder-heads may be given a thickness, at the edges and in the flanges, exceeding somewhat that of the cylinder. An excess of not less than 25% is usual. It may be thinner in the middle. Where made, as is usual in large engines, of two disks with intermediate radiating, connecting ribs or webs, that section which is safe against shearing is probably ample. An examination of the designs of experienced builders, by Professor Thurston, gave

$$t = \frac{Dp}{3000} + \frac{1}{4} \text{ inch,} \quad \dots \dots \dots (1)$$

$D$  being the diameter of that circle in which the thickness is taken.

Thurston also gives  $t = .005D \sqrt{p} + 0.25$ . ..... (2)

Marks gives  $t = 0.003D \sqrt{p}$ . ..... (3)

He also says a good practical rule for pressures under 100 lbs. per sq. in. is to make the thickness of the cylinder-heads  $1\frac{1}{4}$  times that of the walls, and applying this factor to his formula for thickness of walls, or  $.00028pD$ , we have

$$t = .00035pD. \quad \dots \dots \dots (4)$$

Whitham quotes from Seaton,

$$t = \frac{pD + 500}{2000}, \text{ which is equal to } .0005pD + .25 \text{ inch.} \quad \dots \dots (5)$$

Seaton's formula for cylinder bottoms, quoted above, is

$$t = 1.1f, \text{ in which } f = .0002pD + .85 \text{ inch, or } t = .00022pD + .93. \quad \dots (6)$$

Applying the above formulæ to the engines of 10, 30, and 50 inches diameter, with maximum unbalanced steam-pressure of 100 lbs. per sq. in., we have

Cylinder diameter, inches =	10	30	50
(1) $t = .00033Dp + .25$	= .53	1.25	1.82
(2) $t = .005D \sqrt{p} + .25$	= .75	1.75	2.75
(3) $t = .003D \sqrt{p}$	= .30	.90	1.50
(4) $t = .00035Dp$	= .35	1.05	1.75
(5) $t = .0005Dp + .25$	= .75	1.75	2.75
(6) $t = .00022Dp + .93$	= 1.15	1.59	2.03
Average of 6 .....	.65	1.38	2.10

The average is expressed by the formula  $t = .00036Dp + .31$  inch.

Meyer's "Modern Locomotive Construction," p. 24, gives for locomotive cylinder-heads for pressures up to 120 lbs.:

For diameters, in.....	19 to 22	16 to 18	14 to 15	11 to 13	9 to 10
Thickness, in... ..	1¼	1	1	¾	¾

Taking the pressure at 120 lbs. per sq. in., the thicknesses 1¼ in. and ¾ in. for cylinders 22 and 10 in. diam., respectively, correspond to the formula  $t = .00035Dp + .33$  inch.

**Web-stiffened Cylinder-covers.**—Seaton objects to webs for stiffening cast-iron cylinder-covers as a source of danger. The strain on the web is one of tension, and if there should be a nick or defect in the outer edge of the web the sudden application of strain is apt to start a crack. He recommends that high-pressure cylinders over 24 in. and low-pressure cylinders over 40 in. diam. should have their covers cast hollow, with two thicknesses of metal. The depth of the cover at the middle should be about ¼ the diam. of the piston for pressures of 80 lbs. and upwards, and that of the low-pressure cylinder-cover of a compound engine equal to that of the high-pressure cylinder. Another rule is to make the depth at the middle not less than 1.3 times the diameter of the piston-rod. In the British Navy the cylinder-covers are made of steel castings, ¾ to 1¼ in. thick, generally cast without webs, stiffness being obtained by their form, which is often a series of corrugations.

**Cylinder-head Bolts.**—Diameter of bolt-circle for cylinder-head = diameter of cylinder + 2 × thickness of cylinder + 2 × diameter of bolts. The bolts should not be more than 6 inches apart (Whitham).

Marks gives for number of bolts  $b = \frac{.7854D^2p}{5000c} = .0001571\frac{D^2p}{c}$ , in which  $c =$  area of a single bolt,  $p =$  boiler-pressure in lbs. per sq. in.; 5000 lbs. is taken as the safe strain per sq. in. on the nominal area of the bolt.

Seaton says: Cylinder-cover studs and bolts, when made of steel, should be of such a size that the strain in them does not exceed 5000 lbs. per sq. in. When of less than ⅞ inch diameter it should not exceed 4500 lbs. per sq. in. When of iron the strain should be 20% less.

Thurston says: Cylinder flanges are made a little thicker than the cylinder, and usually of equal thickness with the flanges of the heads. Cylinder-bolts should be so closely spaced as not to allow springing of the flanges and leakage, say, 4 to 5 times the thickness of the flanges. Their diameter should be proportioned for a maximum stress of not over 4000 to 5000 lbs. per square inch.

If  $D =$  diameter of cylinder,  $p =$  maximum steam-pressure,  $b =$  number of bolts,  $s =$  size or diameter of each bolt, and 5000 lbs. be allowed per sq. in. of nominal area of the bolt,  $.7854D^2p = 3927bs^2$ ; whence  $bs^2 = .0002D^2p$ ;

$b = .0002\frac{D^2p}{s^2}$ ;  $s = .01414D\sqrt{\frac{p}{b}}$ . For the three engines we have:

Diameter of cylinder, inches.....	10	30	50
Diameter of bolt-circle, approx ....	13	35	57.5
Circumference of circle, approx....	40.8	110	180
Minimum No. of bolts, circ. + 6.....	7	18	30
Diam. of bolts, $s = .01414D\sqrt{\frac{p}{b}}$ .....	¾ in.	1.00	1.29

The diameter of bolt for the 10-inch cylinder is 0.54 in. by the formula, but ¾ inch is as small as should be taken, on account of possible overstrain by the wrench in screwing up the nut.

**The Piston. Details of Construction of Ordinary Pistons.** (Seaton.)—Let  $D$  be the diameter of the piston in inches,  $p$  the effective pressure per square inch on it,  $x$  a constant multiplier, found as follows:

$$x = \frac{D}{50} \times \sqrt{p} + 1.$$

The thickness of front of piston near the boss	=	0.2	×	$x$
“ “ “ “ rim	=	0.17	×	$x$ .
“ back “	=	0.18	×	$x$ .
“ boss around the rod	=	0.3	×	$x$ .
“ flange inside packing-ring	=	0.23	×	$x$ .
“ “ at edge	=	0.25	×	$x$ .
“ packing-ring	=	0.15	×	$x$ .
“ junk-ring at edge	=	0.23	×	$x$ .
“ “ inside packing-ring	=	0.21	×	$x$ .
“ “ at bolt-holes	=	0.35	×	$x$ .
“ metal around piston edge	=	0.25	×	$x$ .
The breadth of packing-ring	=	0.63	×	$x$ .
“ depth of piston at centre	=	1.4	×	$x$ .
“ lap of junk-ring on the piston	=	0.45	×	$x$ .
“ space between piston body and packing-ring	=	0.3	×	$x$ .
“ diameter of junk-ring bolts	=	0.1	×	$x + 0.25$ in.
“ pitch “ “ “	=	10	×	diameters.
“ number of webs in the piston	=	$(D + 20) \div 12$ .		
“ thickness “ “ “	=	0.18	×	$x$ .

Marks gives the approximate rule: Thickness of piston-head =  $\sqrt[4]{ld}$ , in which  $l$  = length of stroke, and  $d$  = diameter of cylinder in inches. Whitham says in a horizontal engine the rings support the piston, or at least a part of it, under ordinary conditions. The pressure due to the weight of the piston upon an area equal to 0.7 the diameter of the cylinder  $\times$  breadth of ring-face should never exceed 200 lbs. per sq. in. He also gives a formula much used in this country: Breadth of ring-face =  $0.15 \times$  diameter of cylinder.

For our engines we have diameter = .....	10	30	50
	Thickness of piston-head.		
Marks, $\sqrt[4]{lD}$ ; long stroke.. .....	3.31	5.48	7.00
Marks, “ ; short stroke.....	3.94	6.51	8.32
Seaton, depth at centre = $1.4x$ .....	4.30	9.80	15.40
Seaton, breadth of ring = $.63x$ .....	1.89	4.41	6.93
Whitham, breadth of ring = $.15D$ .....	1.50	4.50	7.50

**Diameter of Piston Packing-rings.** — These are generally turned, before they are cut, about  $\frac{1}{4}$  inch diameter larger than the cylinder, for cylinders up to 20 inches diameter, and then enough is cut out of the ring to spring them to the diameter of the cylinder. For larger cylinders the rings are turned proportionately larger. Seaton recommends an excess of 1% of the diameter of the cylinder.

**Cross-section of the Rings.**—The thickness is commonly made  $\frac{1}{30}$ th of the diam. of cyl. +  $\frac{1}{8}$  inch, and the width = thickness +  $\frac{1}{8}$  inch. For an eccentric ring the mean thickness may be the same as for a ring of uniform thickness, and the minimum thickness =  $\frac{2}{3}$  the maximum.

A circular issued by J. H. Dunbar, manufacturer of packing-rings, Youngstown, O., says: Unless otherwise ordered, the thickness of rings will be made equal to  $.03 \times$  their diameter. This thickness has been found to be satisfactory in practice. It admits of the ring being made about  $\frac{3}{16}$ " to the foot larger than the cylinder, and has, when new, a tension of about two pounds per inch of circumference, which is ample to prevent leakage, if the surface of the ring and cylinder are smooth.

As regards the width of rings, authorities “scatter” from very narrow to very wide, the latter being fully ten times the former. For instance, Unwin gives  $W = d .014 + .08$ . Whitham’s formula is  $W = d .15$ . In both formulæ  $W$  is the width of the ring in inches, and  $d$  the diameter of the cylinder in inches. Unwin’s formula makes the width of a 20" ring  $W = 20 \times .014 + .08 = .36$ ", while Whitham’s is  $20 \times .15 = 3$ " for the same diameter of ring. There is much less difference in the practice of engine-builders in this respect, but there is still room for a standard width of ring. It is believed that for cylinders over 16" diameter  $\frac{3}{4}$ " is a popular and practical width, and  $\frac{1}{2}$ " for cylinders of that size and under.

**Fit of Piston-rod into Piston.** (Seaton.)—The most convenient and reliable practice is to turn the piston-rod end with a shoulder of  $\frac{1}{16}$  inch for small engines, and  $\frac{1}{8}$  inch for large ones, make the taper 8 in. to

the foot until the section of the rod is three fourths of that of the body, then turn the remaining part parallel; the rod should then fit into the piston so as to leave  $\frac{1}{8}$  inch between it and the shoulder for large pistons, and  $\frac{1}{16}$  in. for small. The shoulder prevents the rod from splitting the piston, and allows of the rod being turned true after long wear without encroaching on the taper.

The piston is secured to the rod by a nut, and the size of the rod should be such that the strain on the section at the bottom of the thread does not exceed 5500 lbs. per sq. in. for iron, 7000 lbs. for steel. The depth of this nut need not exceed the diameter which would be found by allowing these strains. The nut should be locked to prevent its working loose.

**Diameter of Piston-rods.**—Unwin gives

$$d'' = bD \sqrt{p}, \dots \dots \dots (1)$$

in which  $D$  is the cylinder diameter in inches,  $p$  is the maximum unbalanced pressure in lbs. per sq. in., and the constant  $b = 0.0167$  for iron, and  $b = 0.0144$  for steel. Thurston, from an examination of a considerable number of rods in use, gives

$$d'' = \sqrt[4]{\frac{D^2 p L^2}{a}} + \frac{D}{80}, \text{ nearly, } \dots \dots \dots (2)$$

( $L$  in feet,  $D$  and  $d$  in inches), in which  $a = 10,000$  and upward in the various types of engines, the marine screw engines or ordinary fast engines on shore given the lowest values, while "low-speed engines" being less liable to accident from shock give  $a = 15,000$ , often.

Connections of the piston-rod to the piston and to the crosshead should have a factor of safety of at least 8 or 10. Marks gives

$$d'' = 0.0179D \sqrt{p}, \text{ for iron; for steel } d'' = 0.0105D \sqrt{p}; \dots (3)$$

$$\text{and } d'' = 0.03901 \sqrt[4]{D^2 l^2 p}, \text{ for iron; for steel } d'' = 0.03525 \sqrt[4]{D^2 l^2 p}, (4)$$

in which  $l$  is the length of stroke, all dimensions in inches. Deduce the diameter of piston-rod by (3), and if this diameter is less than  $\frac{1}{12}l$ , then use (4).

$$\text{Seaton gives: Diameter of piston-rod} = \frac{\text{Diameter of cylinder}}{F} \sqrt{p}.$$

The following are the values of  $F$ :

Naval engines, direct-acting .....	$F = 60$
“ “ return connecting-rod, 2 rods.....	$F = 80$
Mercantile ordinary stroke, direct-acting.....	$F = 50$
“ long “ “ .....	$F = 48$
“ very long “ “ .....	$F = 45$
“ medium stroke, oscillating .. ..	$F = 45$

**NOTE.**—Long and very long, as compared with the stroke usual for the power of engine or size of cylinder.

In considering an expansive engine  $p$ , the effective pressure should be taken as the absolute working pressure, or 15 lbs. above that to which the boiler safety-valve is loaded; for a compound engine the value of  $p$  for the high-pressure piston should be taken as the absolute pressure, less 15 lbs., or the same as the load on the safety-valve; for the medium-pressure the load may be taken as that due to half the absolute boiler-pressure; and for the low-pressure cylinder the pressure to which the escape-valve is loaded + 15 lbs., or the maximum absolute pressure, which can be got in the receiver, or about 25 lbs. It is an advantage to make all the rods of a compound engine alike, and this is now the rule.

Applying the above formulæ to the engines of 10, 30, and 50 in. diameter, both short and long stroke, we have:

## Diameter of Piston-rods.

Diameter of Cylinder, inches.....	10		30		50	
Stroke, inches.....	12	24	30	60	48	96
Unwin, iron, $.0167D \sqrt{p}$ .....	1.67	1.67	5.01	5.01	8.35	8.35
Unwin, steel, $.0144D \sqrt{p}$ .....	1.44	1.44	4.32	4.32	7.20	7.20
Thurston $\sqrt[4]{\frac{D^2 p L^2}{10,000} + \frac{D}{80}}$ ( $L$ in feet).	1.13	.....	3.12	.....	5.10	.....
Thurston, same with $a = 15,000$ .....	.....	1.40	.....	3.88	.....	6.35
Marks, iron, $.0179D \sqrt{p}$ .....	1.79	.....	5.37	5.37	8.95	8.95
Marks, iron, $.03901 \sqrt[4]{D^2 l^2 p}$ .....	1.35	1.91	3.70	5.13	6.04	8.54
Marks, steel, $.0105D \sqrt{p}$ .....	(1.05)	.....	(3.15)	.....	(5.25)	.....
Marks, steel, $.03525 \sqrt[4]{D^2 l^2 p}$ .....	1.22	1.73	3.34	4.72	5.46	7.72
Seaton, naval engines, $\frac{D}{60} \sqrt{p}$ .....	1.67	.....	5.01	.....	8.35	.....
Seaton, land engine, $\frac{D}{45} \sqrt{p}$ .....	.....	2.22	.....	6.67	.....	11.11
Average of four for iron.....	1.49	1.82	4.30	5.26	7.11	8.74

The figures in brackets opposite Marks' third formula would be rejected since they are less than  $\frac{1}{8}$  of the stroke, and the figures derived by his fourth formula would be taken instead. The figure 1.79 opposite his first formula would be rejected for the engine of 24-inch stroke.

An empirical formula which gives results approximating the above averages is  $d' = .013 \sqrt{Dlp}$ .

The calculated results from this formula, for the six engines, are, respectively, 1.42, 1.88, 3.90, 5.61, 6.37, 9.01.

**Piston-rod Guides.**—The thrust on the guide, when the connecting-rod is at its maximum angle with the line of the piston-rod, is found from the formula: Thrust = total load on piston  $\times$  tangent of maximum angle of connecting-rod =  $p \tan \theta$ . This angle,  $\theta$ , is the angle whose sine = half stroke of piston  $\div$  length of connecting-rod.

Ratio of length of connecting-rod to stroke.....	2	2½	3
Maximum angle of connecting-rod with line of piston-rod.....	14° 29'	11° 33'	9° 36'
Tangent of the angle.....	.258	.204	.169
Secant of the angle.....	1.0327	1.0206	1.014

Seaton says: The area of the guide-block or slipper surface on which the thrust is taken should in no case be less than will admit of a pressure of 400 lbs. on the square inch; and for good working those surfaces which take the thrust when going ahead should be sufficiently large to prevent the maximum pressure exceeding 100 lbs. per sq. in. When the surfaces are kept well lubricated this allowance may be exceeded.

Thurston says: The rubbing surfaces of guides are so proportioned that if  $V$  be their relative velocity in feet per minute, and  $p$  be the intensity of pressure on the guide in lbs. per sq. in.,  $pV < 60,000$  and  $pV > 40,000$ .

The lower is the safer limit; but for marine and stationary engines it is allowable to take  $p = 60,000 \div V$ . According to Rankine, for locomotives,

$p = \frac{44800}{V + 20}$ , where  $p$  is the pressure in lbs. per sq. in. and  $V$  the velocity of rubbing in feet per minute. This includes the sum of all pressures forcing the two rubbing surfaces together.

Some British builders of portable engines restrict the pressure between the guides and cross-heads to less than 40, sometimes 35 lbs. per square inch.

For a mean velocity of 600 feet per minute, Prof. Thurston's formulas give,  $p < 100$ ,  $p > 66.7$ ; Rankine's gives  $p = 72.2$  lbs. per sq. in.

Whitham gives,

$$A = \text{area of slides in square inches} = \frac{P}{p_0 \sqrt{n^2 - 1}} = \frac{.7854d^2 p_1}{p_0 \sqrt{n^2 - 1}},$$

in which  $P$  = total unbalanced pressure,  $p_1$  = pressure per square inch on piston,  $d$  = diameter of cylinder,  $p_0$  = pressure allowable per square inch on slides, and  $n$  = length of connecting-rod  $\div$  length of crank. This is equivalent to the formula,  $A = P \tan \theta \div p_0$ . For  $n = 5$ ,  $p_1 = 100$  and  $p_0 = 80$ ,  $A = .2004d^2$ . For the three engines 10, 30 and 50 in. diam., this would give for area of slides,  $A = 20, 180$  and  $500$  sq. in., respectively. Whitham says: The normal pressure on the slide may be as high as 500 lbs. per sq. in., but this is when there is good lubrication and freedom from dust. Stationary and marine engines are usually designed to carry 100 lbs. per sq. in., and the area in this case is reduced from 50% to 60% by grooves. In locomotive engines the pressure ranges from 40 to 50 lbs. per sq. in. of slide, on account of the inaccessibility of the slide, dirt, cinder, etc.

There is perfect agreement among the authorities as to the formula for area of the slides,  $A = P \tan \theta \div p_0$ ; but the value given to  $p_0$ , the allowable pressure per square inch, ranges all the way from 35 lbs. to 500 lbs.

**The Connecting-rod.** *Ratio of length of connecting-rod to length of stroke.*—Experience has led generally to the ratio of 2 or  $2\frac{1}{2}$  to 1, the latter giving a long and easy-working rod, the former a rather short, but yet a manageable one (Thurston). Whitham gives the ratio of from 2 to  $4\frac{1}{2}$ , and Marks from 2 to 4.

*Dimensions of the Connecting-rod.*—The calculation of the diameter of a connecting-rod on a theoretical basis, considering it as a strut subject to both compressive and bending stresses, and also to stress due to its inertia, in high-speed engines, is quite complicated. See Whitham, *Steam-engine Design*, p. 217; Thurston, *Manual of S. E.*, p. 100. Empirical formulas are as follows: For circular rods, largest at the middle,  $D$  = diam. of cylinder,  $l$  = length of connecting-rod in inches,  $p$  = maximum steam-pressure per sq. in.

(1) Whitham, diam. at middle,  $d'' = 0.0272 \sqrt{Dl \sqrt{p}}$ .

(2) Whitham, diam. at necks,  $d'' = 1.0$  to  $1.1 \times$  diam. of piston-rod.

(3) Sennett, diam. at middle,  $d'' = \frac{D}{55} \sqrt{p}$ .

(4) Sennett, diam. at necks,  $d'' = \frac{D}{60} \sqrt{p}$ .

(5) Marks, diam.,  $d'' = 0.0179D \sqrt{p}$ , if diam. is greater than  $1/24$  length.

(6) Marks, diam.,  $d'' = 0.02758 \sqrt{Dl \sqrt{p}}$  if diam. found by (5) is less than  $1/24$  length.

(7) Thurston, diam. at middle,  $d'' = a \sqrt{DL \sqrt{p}} + C$ ,  $D$  in inches,  $L$  in feet,  $a = 0.15$  and  $C = \frac{1}{2}$  inch for fast engines,  $a = 0.08$  and  $C = \frac{3}{4}$  inch for moderate speed.

(8) Seaton says: The rod may be considered as a strut free at both ends, and, calculating its diameter accordingly,

$$\text{diameter at middle} = \frac{\sqrt{R(1 + 4ar^2)}}{48.5},$$

where  $R$  = the total load on piston  $P$  multiplied by the secant of the maximum angle of obliquity of the connecting-rod.

For wrought iron and mild steel  $a$  is taken at  $1/3000$ . The following are the values of  $r$  in practice:

Naval engines—Direct-acting	$r = 9$ to $11$ ;
“ “ Return connecting-rod	$r = 10$ to $13$ , old;
“ “ “ “	$r = 8$ to $9$ , modern;
“ “ Trunk	$r = 11.5$ to $13$ .
Mercantile “ Direct-acting, ordinary	$r = 12$ .
“ “ “ long stroke	$r = 13$ to $16$ .

(9) The following empirical formula is given by Seaton as agreeing closely with good modern practice:

Diameter of connecting-rod at middle =  $\sqrt{IK} \div 4$ ,  $l$  = length of rod in inches, and  $K = 0.03 \sqrt{\text{effective load on piston in pounds}}$ .

The diam. at the ends may be 0.875 of the diam. at the middle.

Seaton's empirical formula when translated into terms of  $D$  and  $p$  is the same as the second one by Marks, viz.,  $d'' = 0.02758 \sqrt{DL \sqrt{p}}$ . Whitham's (1) is also practically the same.

(10) Taking Seaton's more complex formula, with length of connecting-rod =  $2.5 \times$  length of stroke, and  $r = 12$  and  $16$ , respectively, it reduces to: Diam. at middle =  $.02294 \sqrt{P}$  and  $.02411 \sqrt{P}$  for short and long stroke engines, respectively.

Applying the above formulas to the engines of our list, we have

**Diameter of Connecting-rods.**

Diameter of Cylinder, inches.....	10		30		50	
Stroke, inches.....	12	24	30	60	48	96
Length of connecting-rod $l$ .....	30	60	75	150	120	240
(3) $d'' = \frac{D}{55} \sqrt{p} = .0182D \sqrt{p}$ .....	1.82	1.82	5.46	5.46	9.09	9.09
(5) $d'' = .0179D \sqrt{p}$ .....	1.79	.....	5.37	.....	8.95	.....
(6) $d'' = .02758 \sqrt{DL \sqrt{p}}$ .....	.....	2.14	.....	5.85	.....	9.51
(7) $d'' = 0.15 \sqrt{DL \sqrt{p}} + \frac{1}{2}$ .....	2.87	.....	7.00	.....	11.11	.....
(7) $d'' = 0.08 \sqrt{DL \sqrt{p}} + \frac{3}{4}$ .....	.....	2.54	.....	5.65	.....	8.75
(9) $d'' = .03 \sqrt{P}$ .....	2.67	2.67	7.97	7.97	13.29	13.29
(10) $d'' = .02294 \sqrt{P}; .02411 \sqrt{P}$ .....	2.03	2.14	6.09	6.41	10.16	10.68
Average.....	2.24	2.26	6.38	6.27	10.52	10.26

Formulae 5 and 6 (Marks), and also formula 10 (Seaton), give the larger diameters for the long-stroke engine; formulae 7 give the larger diameters for the short-stroke engines. The average figures show but little difference in diameter between long- and short-stroke engines; this is what might be expected, for while the connecting-rod, considered simply as a column, would require an increase of diameter for an increase of length, the load remaining the same, yet in an engine generally the shorter the connecting-rod the greater the number of revolutions, and consequently the greater the strains due to inertia. The influences tending to increase the diameter therefore tend to balance each other, and to render the diameter to some extent independent of the length. The average figures correspond nearly to the simple formula  $d'' = .021D \sqrt{p}$ . The diameters of rod for the three diameters of engine by this formula are, respectively, 2.10, 6.30, and 10.50 in. Since the total pressure on the piston  $P = .7854D^2p$ , the formula is equivalent to  $d'' = .0237 \sqrt{P}$ .

**Connecting-rod Ends.**—For a connecting-rod end of the marine type, where the end is secured with two bolts, each bolt should be proportioned for a safe tensile strength equal to two thirds the maximum pull or thrust in the connecting-rod.

The cap is to be proportioned as a beam loaded with the maximum pull of the connecting-rod, and supported at both ends. The calculation should be made for rigidity as well as strength, allowing a maximum deflection of 1/100 inch. For a strap-and-key connecting-rod end the strap is designed for tensile strength, considering that two thirds of the pull on the connecting-rod may come on one arm. At the point where the metal is slotted for the key and gib, the straps must be thickened to make the cross-section equal to that of the remainder of the strap. Between the end of the strap and the slot the strap is liable to fail in double shear, and sufficient metal must be provided at the end to prevent such failure.

The breadth of the key is generally one fourth of the width of the strap, and the length, parallel to the strap, should be such that the cross-section will have a shearing strength equal to the tensile strength of the section of the strap. The taper of the key is generally about  $\frac{5}{8}$  inch to the foot.

**Tapered Connecting-rods.**—In modern high-speed engines it is customary to make the connecting-rods of rectangular instead of circular section, the sides being parallel, and the depth increasing regularly from the crosshead end to the crank-pin end. According to Grashof, the bending action on the rod due to its inertia is greatest at 6/10 the length from the crosshead end, and, according to this theory, that is the point at which the section should be greatest, although in practice the section is made greatest at the crank-pin end.

Professor Thurston furnishes the author with the following rule for tapered connecting-rod of rectangular section: Take the section as computed by the

formula  $d'' = 0.1\sqrt{DL\sqrt{p}} + 3/4$  for a circular section, and for a rod 4/3 the actual length, placing the computed section at 2/3 the length from the small end, and carrying the taper straight through this fixed section to the large end. This brings the computed section at the surge point and makes it heavier than the rod for which a tapered form is not required.

Taking the above formula, multiplying  $L$  by 4/3, and changing it to  $l$  in inches, it becomes  $d = 1/30\sqrt{Dl\sqrt{p}} + 3/4''$ . Taking a rectangular section of the same area as the round section whose diameter is  $d$ , and making the depth of the section  $h =$  twice the thickness  $t$ , we have  $.7854d^2 = ht = 2t^2$ ,

whence  $t = .627d = .0209\sqrt{Dl\sqrt{p}} + .47''$ , which is the formula for the thickness or distance between the parallel sides of the rod. Making the depth at the crosshead end  $= 1.5t$ , and at 2/3 the length  $= 2t$ , the equivalent depth at the crank end is  $2.25t$ . Applying the formula to the short-stroke engines of our examples, we have

Diameter of cylinder, inches.....	10	30	50
Stroke, inches.....	12	80	48
Length of connecting-rod.....	30	75	120
Thickness, $t = .0209\sqrt{Dl\sqrt{p}} + .47 =$ .....	1.61	3.60	5.59
Depth at crosshead end, $1.5t =$ .....	2.42	5.41	8.39
Depth at crank end, $2\frac{1}{4}t$ .....	3.62	8.11	12.58

The thicknesses  $t$ , found by the formula  $t = .0209\sqrt{Dl\sqrt{p}} + .47$ , agree closely with the more simple formula  $t = .01D\sqrt{p} + .60''$ , the thicknesses calculated by this formula being respectively 1.6, 3.6, and 5.6 inches.

**The Crank-pin.**—A crank-pin should be designed (1) to avoid heating, (2) for strength, (3) for rigidity. The heating of a crank-pin depends on the pressure on its rubbing-surface, and on the coefficient of friction, which latter varies greatly according to the effectiveness of the lubrication. It also depends upon the facility with which the heat produced may be carried away: thus it appears that locomotive crank-pins may be prevented to some degree from overheating by the cooling action of the air through which they pass at a high speed.

$$\text{Marks gives } l = .0000247 fpND^2 = 1.038f \frac{(\text{I.H.P.})}{L} \dots \dots \dots (1)$$

$$\text{Whitham gives } l = 0.9075f \frac{(\text{I.H.P.})}{L}, \dots \dots \dots (2)$$

In which  $l =$  length of crank-pin journal in inches,  $f =$  coefficient of friction, which may be taken at .03 to .05 for perfect lubrication, and .08 to .10 for imperfect;  $p =$  mean pressure in the cylinder in pounds per square inch;  $D =$  diameter of cylinder in inches;  $N =$  number of single strokes per minute; I.H.P. = indicated horse-power;  $L =$  length of stroke in feet. These formulæ are independent of the diameter of the pin, and Marks states as a general law, within reasonable limits as to pressure and speed of rubbing, the longer a bearing is made, for a given pressure and number of revolutions, the cooler it will work; and its diameter has no effect upon its heating. Both of the above formulæ are deduced empirically from dimensions of crank-pins of existing marine engines. Marks says that about one-fourth the length required for crank-pins of propeller engines will serve for the pins of side-wheel engines, and one-tenth for locomotive engines, making the

formula for locomotive crank-pins  $l = .00000247fpND^2$ , or if  $p = 150$ ,  $f = .06$ , and  $N = 600$ ,  $l = .013D^2$ .

Whitham recommends for pressure per square inch of projected area, for naval engines 500 pounds, for merchant engines 400 pounds, for paddle-wheel engines 800 to 900 pounds.

Thurston says the pressure should, in the steam-engine, never exceed 500 or 600 pounds per square inch for wrought-iron pins, or about twice that figure for steel. He gives the formula for length of a steel pin, in inches,

$$l = PR \div 600,000, \dots \dots \dots (3)$$

in which  $P$  and  $R$  are the mean total load on the pin in pounds, and the number of revolutions per minute. For locomotives, the divisor may be taken as 500,000. Where iron is used this figure should be reduced to 300,000 and 250,000 for the two cases taken. Pins so proportioned, if well made and well lubricated, may always be depended upon to run cool; if not well formed, perfectly cylindrical, well finished, and kept well oiled, no crank-pin can be relied upon. It is assumed above that good bronze or white-metal bearings are used.

Thurston also says: The size of crank-pins required to prevent heating of the journals may be determined with a fair degree of precision by either of the formulæ given below:

$$l = \frac{P(V + 20)}{44,800d} \text{ (Rankine, 1865); } \dots \dots \dots (4)$$

$$l = \frac{PV}{60,000d} \text{ (Thurston, 1862); } \dots \dots \dots (5)$$

$$l = \frac{PN}{850,000} \text{ (Van Buren, 1866). } \dots \dots \dots (6)$$

The first two formulæ give what are considered by their authors fair working proportions, and the last gives minimum length for iron pins. ( $V =$  velocity of rubbing-surface in feet per minute.)

Formula (1) was obtained by observing locomotive practice in which great liability exists of annoyance by dust, and great risk occurs from inaccessibility while running, and (2) by observation of crank-pins of naval screw-engines. The first formula is therefore not well suited for marine practice.

Steel can usually be worked at nearly double the pressure admissible with iron running at similar speed.

Since the length of the crank-pin will be directly as the power expended upon it and inversely as the pressure, we may take it as

$$l = a \frac{\text{I.H.P.}}{L}, \dots \dots \dots (7)$$

in which  $a$  is a constant, and  $L$  the stroke of piston, in feet. The values of the constant, as obtained by Mr. Skeel, are about as follows:  $a = 0.04$  where water can be constantly used;  $a = 0.045$  where water is not generally used;  $a = 0.05$  where water is seldom used;  $a = 0.06$  where water is never needed. Unwin gives

$$l = a \frac{\text{I.H.P.}}{r}, \dots \dots \dots (8)$$

in which  $r =$  crank radius in inches,  $a = 0.3$  to  $a = 0.4$  for iron and for marine engines, and  $a = 0.066$  to  $a = 0.1$  for the case of the best steel and for locomotive work, where it is often necessary to shorten up outside pins as much as possible.

J. B. Stanwood (*Eng'g*, June 12, 1891), in a table of dimensions of parts of American Corliss engines from 10 to 30 inches diameter of cylinder, gives sizes of crank-pins which approximate closely to the formula

$$l = .275D'' + .5 \text{ in.}; \quad d = .25D'' \dots \dots \dots (9)$$

By calculating lengths of iron crank-pins for the engines 10, 30, and 50 inches diameter, long and short stroke, by the several formulæ above given, it is found that there is a great difference in the results, so that one formula in certain cases gives a length three times as great as another. Nos. (4), (5), and (6) give lengths much greater than the others. Marks (1), Whitham (2), Thurston (7),  $l = .06 \text{ I.H.P.} \div L$ , and Unwin (8),  $l = 0.4 \text{ I.H.P.} \div r$ , give results which agree more closely.

The calculated lengths of iron crank-pins for the several cases by formulæ (1), (2), (7), and (8) are as follows:

**Length of Crank-pins.**

Diameter of cylinder..... <i>D</i>	10	10	30	30	50	50
Stroke..... <i>L</i> (ft.)	1	2	2½	5	4	8
Revolutions per minute..... <i>R</i>	250	125	130	65	90	45

(3) Thurston, steel, $l = \frac{PR}{600,000}$ .....	1.37	.69	4.95	2.47	8.84	4.42

The calculated lengths for the long-stroke engines are too low to prevent excessive pressures. See "Pressures on the Crank-pins," below.

**The Strength of the Crank-pin** is determined substantially as is that of the crank. In overhung cranks the load is usually assumed as carried at its extremity, and, equating its moment with that of the resistance of the pin,

$$\frac{1}{2}Pl = 1/32t\pi d^3, \text{ and } d = \sqrt[3]{\frac{5.1Pl}{t}},$$

in which *d* = diameter of pin in inches, *P* = maximum load on the piston, *t* = the maximum allowable stress on a square inch of the metal. For iron it may be taken at 9000 lbs. For steel the diameters found by this formula may be reduced 10%. (Thurston.)

Unwin gives the same formula in another form, viz.:

$$d = \sqrt[3]{\frac{5.1}{t}} \sqrt[3]{Pl} = \sqrt{\frac{5.1}{t}} \sqrt{\frac{l}{Pd}}$$

the last form to be used when the ratio of length to diameter is assumed.

For wrought iron, *t* = 6000 to 9000 lbs. per sq. in.,

$$\sqrt[3]{\frac{5.1}{t}} = .0947 \text{ to } .0827; \quad \sqrt{\frac{5.1}{t}} = .0291 \text{ to } .0238.$$

For steel, *t* = 9000 to 13,000 lbs. per sq. in.,

$$\sqrt[3]{\frac{5.1}{t}} = .0827 \text{ to } .0723; \quad \sqrt{\frac{5.1}{t}} = .0238 \text{ to } .0194.$$

Whitham gives  $d = 0.0827 \sqrt[3]{Pl} = 2.1058 \sqrt[3]{\frac{l \times \text{I.H.P.}}{LR}}$  for strength, and

$d = 0.0405 \sqrt[4]{Pl^3}$  for rigidity, and recommends that the diameter be calculated by both formulæ, and the largest result taken. The first is the same as Unwin's formula, with *t* taken at 9000 lbs. per sq. in. The second is based upon an arbitrary assumption of a deflection of 1-300 in. at the centre of pressure (one third of the length from the free end).

ing-rod, and working in brasses fitted into a recess in the piston-rod end and secured by a wrought-iron cap and two bolts, Seaton gives:

- Diameter of gudgeon = 1.25 × diam. of piston-rod.
- Length of gudgeon = 1.4 × diam. of piston-rod.

If the pressure on the section, as calculated by multiplying length by diameter, exceeds 1200 lbs. per sq. in., this length should be increased.

J. B. Stanwood, in his "Ready Reference" book, gives for length of crosshead-pin 0.25 to 0.3 diam. of piston, and diam. = 0.18 to 0.2 diam. of piston. Since he gives for diam. of piston-rod 0.14 to 0.17 diam. of piston, his dimensions for diameter and length of crosshead-pin are about 1.25 and 1.8 diam. of piston-rod respectively. Taking the maximum allowable pressure at 1200 lbs. per sq. in. and making the length of the crosshead-pin = 4/3 of its diameter, we have  $d = \sqrt{P} + 40$ ,  $l = \sqrt{P} + 30$ , in which  $P$  = maximum total load on piston in lbs.,  $d$  = diam. and  $l$  = length of pin in inches. For the engines of our example we have:

Diameter of piston, inches.....	10	30	50
Maximum load on piston, lbs.....	7854	70,686	196,350
Diameter of crosshead-pin, inches.....	2.22	6.65	11.08
Length of crosshead-pin, inches....	2.96	8.86	14.77
Stanwood's rule gives diameter, inches.....	1.8 to 2	5.4 to 6	9.0 to 10
Stanwood's rule gives length, inches.....	2.5 to 3	7.5 to 9	12.5 to 15
Stanwood's largest dimensions give pressure per sq. in., lbs .....	1309	1329	1309

Which pressures are greater than the maximum allowed by Seaton.

**The Crank-arm.**—The crank-arm is to be treated as a lever, so that if  $a$  is the thickness in direction parallel to the shaft-axis and  $b$  its breadth at a section  $x$  inches from the crank-pin centre, then, bending moment  $M$  at that section =  $Px$ ,  $P$  being the thrust of the connecting-rod, and  $f$  the safe strain per square inch,

$$Px = \frac{fab^2}{6} \text{ and } \frac{a \times b^2}{6} = \frac{T}{f} \text{ or } a = \frac{6T}{b^2 \times f}; b = \sqrt{\frac{6T}{fa}}$$

If a crank-arm were constructed so that  $b$  varied as  $\sqrt{x}$  (as given by the above rule) it would be of such a curved form as to be inconvenient to manufacture, and consequently it is customary in practice to find the maximum value of  $b$  and draw tangent lines to the curve at the points; these lines are generally, for the same reason, tangential to the boss of the crank-arm at the shaft.

The shearing strain is the same throughout the crank-arm; and, consequently, is large compared with the bending strain close to the crank-pin; and so it is not sufficient to provide there only for bending strains. The section at this point should be such that, in addition to what is given by the calculation from the bending moment, there is an extra square inch for every 8000 lbs. of thrust on the connecting-rod (Seaton).

The length of the boss  $h$  into which the shaft is fitted is from 0.75 to 1.0 of the diameter of the shaft  $D$ , and its thickness  $e$  must be calculated from the twisting strain  $PL$ . ( $L$  = length of crank.)

For different values of length of boss  $h$ , the following values of thickness of boss  $e$  are given by Seaton:

- When  $h = D$ , then  $e = 0.35 D$ ; if steel, 0.3.
- $h = 0.9 D$ , then  $e = 0.38 D$ , if steel, 0.32.
- $h = 0.8 D$ , then  $e = 0.40 D$ , if steel, 0.33.
- $h = 0.7 D$ , then  $e = 0.41 D$ , if steel, 0.34.

The crank-eye or boss into which the pin is fitted should bear the same relation to the pin that the boss does to the shaft.

The diameter of the shaft-end onto which the crank is fitted should be 1.1 × diameter of shaft.

Thurston says: The empirical proportions adopted by builders will commonly be found to fall well within the calculated safe margin. These proportions are, from the practice of successful designers, about as follows:

For the wrought-iron crank, the hub is 1.75 to 1.8 times the least diameter of that part of the shaft carrying full load; the eye is 2.0 to 2.25 the diameter of the inserted portion of the pin, and their depths are, for the hub, 1.0 to 1.2 the diameter of shaft, and for the eye, 1.25 to 1.5 the diameter of pin.

The web is made 0.7 to 0.75 the width of adjacent hub or eye, and is given a depth of 0.5 to 0.6 that of adjacent hub or eye.

For the cast-iron crank the hub and eye are a little larger, ranging in diameter respectively from 1.8 to 2 and from 2 to 2.2 times the diameters of shaft and pin. The flanges are made at either end of nearly the full depth of hub or eye. Cast-iron has, however, fallen very generally into disuse.

The crank-shaft is usually enlarged at the seat of the crank to about 1.1 its diameter at the journal. The size should be nicely adjusted to allow for the shrinkage or forcing on of the crank. A difference of diameter of one fifth of 1%, will usually suffice; and a common rule of practice gives an allowance of but one half of this, or .001.

The formulæ given by different writers for crank-arms practically agree, since they all consider the crank as a beam loaded at one end and fixed at the other. The relation of breadth to thickness may vary according to the taste of the designer. Calculated dimensions for our six engines are as follows:

**Dimensions of Crank-arms.**

Diam. of cylinder, ins...	10	10	30	30	50	50

**The Shaft.—Twisting Resistance.**—From the general formula

for torsion, we have:  $T = \frac{\pi}{16} d^3 S = .19635 d^3 S$ , whence  $d = \sqrt[3]{\frac{5.1T}{S}}$ , in which

*T* = torsional moment in inch-pounds, *d* = diameter in inches, and *S* = the shearing resistance of the material in pounds per square inch.

If a constant force *P* were applied to the crank-pin tangentially to its path, the work done per minute would be

$$P \times L \times \frac{2\pi}{12} \times R = 33,000 \times \text{I.H.P.},$$

in which *L* = length of crank in inches, and *R* = revs. per min., and the mean twisting moment  $T = \frac{\text{I.H.P.}}{R} \times 63,025$ . Therefore

$$d = \sqrt[3]{\frac{5.1T}{S}} = \sqrt[3]{\frac{321,427 \text{ I.H.P.}}{RS}}$$

This may take the form

$$d = \sqrt[3]{\frac{\text{I.H.P.}}{R} \times F}, \text{ or } d = a \sqrt[3]{\frac{\text{I.H.P.}}{R}}.$$

In which *F* and *a* are factors that depend on the strength of the material and on the factor of safety. Taking *S* at 45,000 pounds per square inch for wrought iron, and at 60,000 for steel, we have, for simple twisting by a uniform tangential force,

Factor of safety =	5	6	8	10		5	6	8	10
Iron..... <i>F</i> =	35.7	42.8	57.1	71.4		<i>a</i> = 3.3	3.5	3.85	4.15
Steel..... <i>F</i> =	26.8	32.1	42.8	53.5		<i>a</i> = 3.0	3.18	3.5	3.77

Unwin, taking for safe working strength of wrought iron 9000 lbs., steel 13,500 lbs., and cast iron 4500 lbs., gives *a* = 3.294 for wrought iron, 2.877 for steel, and 4.15 for cast iron. Thurston, for crank-axes of wrought iron, gives *a* = 4.15 or more.

Seaton says: For wrought iron, *f*, the safe strain per square inch, should not exceed 9000 lbs., and when the shafts are more than 10 inches diameter, 8000 lbs. Steel, when made from the ingot and of good materials, will admit of a stress of 12,000 lbs. for small shafts, and 10,000 lbs. for those above 10 inches diameter.

The difference in the allowance between large and small shafts is to compensate for the defective material observable in the heart of large shafting, owing to the hammering failing to affect it.

The formula  $d = a \sqrt[3]{\frac{\text{I.H.P.}}{R}}$  assumes the tangential force to be uniform

and that it is the only acting force. For engines, in which the tangential force varies with the angle between the crank and the connecting-rod, and with the variation in steam-pressure in the cylinder, and also is influenced by the inertia of the reciprocating parts, and in which also the shaft may be subjected to bending as well as torsion, the factor *a* must be increased, to provide for the maximum tangential force and for bending.

Seaton gives the following table showing the relation between the maximum and mean twisting moments of engines working under various conditions, the momentum of the moving parts being neglected, which is allowable:

Description of Engine.	Steam Cut-off at	Max. Twist Divided by Mean Twist. Mome't	Cube Root of the Ratio.
Single-crank expansive.....	0.2	2.625	1.38

“ “ “ .....	0.3	1.415	1.12
“ “ “ .....	0.4	1.298	1.09
“ “ “ .....	0.5	1.256	1.08
“ “ “ .....	0.6	1.270	1.08
“ “ “ .....	0.7	1.329	1.10
“ “ “ .....	0.8	1.357	1.11
Three-cylinder compound, cranks 120°....	h.p. 0.5, l.p. 0.66	1.40	1.12
“ “ “ l.p. cranks } opposite one another, and h.p. midway }	“ “	1.26	1.08

Seaton also gives the following rules for ordinary practice for ordinary two-cylinder marine engines:

$$\text{Diameter of the tunnel-shafts} = \sqrt[3]{\frac{\text{I.H.P.}}{R} \times F}, \text{ or } a \sqrt[3]{\frac{\text{I.H.P.}}{R}}.$$

Compound engines, cranks at right angles:

- Boiler pressure 70 lbs., rate of expansion 6 to 7,  $F = 70$ ,  $a = 4.12$ .
- Boiler pressure 80 lbs., rate of expansion 7 to 8,  $F = 72$ ,  $a = 4.16$ .
- Boiler pressure 90 lbs., rate of expansion 8 to 9,  $F = 75$ ,  $a = 4.22$ .

Triple compound, three cranks at 120 degrees:

- Boiler pressure 150 lbs., rate of expansion 10 to 12,  $F = 62$ ,  $a = 3.96$ .
- Boiler pressure 160 lbs., rate of expansion 11 to 13,  $F = 64$ ,  $a = 4$ .
- Boiler pressure 170 lbs., rate of expansion 12 to 15,  $F = 67$ ,  $a = 4.06$ .

Expansive engines, cranks at right angles, and the rate of expansion 5, boiler-pressure 60 lbs.,  $F = 90$ ,  $a = 4.48$ .

Single-crank compound engines, pressure 80 lbs.,  $F = 96$ ,  $a = 4.58$ .

For the engines we are considering it will be a very liberal allowance for ratio of maximum to mean twisting moment if we take it as equal to the ratio of the maximum to the mean pressure on the piston. The factor  $a$ , then, in the formula for diameter of the shaft will be multiplied by the cube

root of this ratio, or  $\sqrt[3]{\frac{100}{42}} = 1.34$ ,  $\sqrt[3]{\frac{100}{32.3}} = 1.45$ , and  $\sqrt[3]{\frac{100}{30}} = 1.49$  for the

10, 30, and 50-in. engines, respectively. Taking  $a = 3.5$ , which corresponds to a shearing strength of 60,000 and a factor of safety of 8 for steel, or to 45,000 and a factor of 6 for iron, we have for the new coefficient  $a$ , in the

formula  $d_1 = a_1 \sqrt[3]{\frac{I.H.P.}{R}}$ , the values 4.69, 5.08, and 5.22, from which we

obtain the diameters of shafts of the six engines as follows:

Engine No.....	1	2	3	4	5	6
Diam. of cyl.....	10	10	30	30	50	50
Horse-power, I.H.P.....	50	50	450	450	1250	1250
Revs. per min., $R$ ....	250	125	130	65	90	45
Diam. of shaft $d = a_1 \sqrt[3]{\frac{I.H.P.}{R}}$ ....	2.74	3.46	7.67	9.70	12.55	15.82

These diameters are calculated for twisting only. When the shaft is also subjected to bending strain the calculation must be modified as below:

**Resistance to Bending.**—The strength of a circular-section shaft to resist bending is one half of that to resist twisting. If  $B$  is the bending moment in inch-lbs., and  $d$  the diameter of the shaft in inches,

$$B = \frac{\pi d^3}{32} \times f; \text{ and } d = \sqrt[3]{\frac{B}{f} \times 10.2};$$

$f$  is the safe strain per square inch of the material of which the shaft is composed, and its value may be taken as given above for twisting (Seaton).

**Equivalent Twisting Moment.**—When a shaft is subject to both twisting and bending simultaneously, the combined strain on any section of it may be measured by calculating what is called the *equivalent twisting moment*; that is, the two strains are so combined as to be treated as a twisting strain only of the same magnitude and the size of shaft calculated accordingly. Rankine gave the following solution of the combined action of the two strains.

If  $T$  = the twisting moment, and  $B$  = the bending moment on a section of a shaft, then the equivalent twisting moment  $T_1 = B + \sqrt{B^2 + T^2}$ .

Seaton says: Crank-shafts are subject always to twisting, bending, and shearing strains; the latter are so small compared with the former that they are usually neglected directly, but allowed for indirectly by means of the factor  $f$ .

The two principal strains vary throughout the revolution, and the maximum equivalent twisting moment can only be obtained accurately by a series of calculations of bending and twisting moments taken at fixed intervals, and from them constructing a curve of strains.

Considering the engines of our examples to have overhung cranks, the maximum bending moment resulting from the thrust of the connecting-rod on the crank-pin will take place when the engine is passing its centres (neglecting the effect of the inertia of the reciprocating parts), and it will be the product of the total pressure on the piston by the distance between

(two parallel lines passing through the centres of the crank-pin and of the shaft bearing, at right angles to their axes; which distance is equal to  $\frac{1}{2}$  length of crank-pin bearing + length of hub +  $\frac{1}{2}$  length of shaft-bearing + any clearance that may be allowed between the crank and the two bearings. For our six engines we may take this distance as equal to  $\frac{1}{2}$  length of crank-pin + thickness of crank-arm +  $1.5 \times$  the diameter of the shaft as already found by the calculation for twisting. The calculation of diameter is then as below:

Engine No.	1	2	3	4	5	6
Diam. of cyl., in. . .	10	10	30	30	50	50
Horse-power.....	50	50	450	450	1250	1250
Revs. per min. . . .	250	125	130	65	90	45
Max.press. on pis, <i>P</i>	7,854	7,854	70,686	70,686	196,350	196,350
Leverage,* <i>L</i> in....	6.32	7.94	22.20	26.00	36.80	42.25
Bd.mo. <i>PL=B</i> in.-lb	49,637	62,361	1,569,222	1,837,836	7,225,680	8,295,788
Twist. mom. <i>T</i> .....	47,124	94,248	1,060,290	2,120,580	4,712,400	9,424,800
Equiv.Twist. mom. $T_1 = B + \sqrt{B^2 + T^2}$ (approx.).....	118,000	175,000	3,463,000	4,647,000	15,840,000	20,850,000

\* Leverage = distance between centres of crank-pin and shaft bearing =  $\frac{1}{2}l + 2.25d$ .

Having already found the diameters, on the assumption that the shafts were subjected to a twisting moment *T* only, we may find the diameter for resisting combined bending and twisting by multiplying the diameters already found by the cube roots of the ratio  $T_1 \div T$ , or

Giving corrected diameters  $d_1 = \dots$  3.84 4.39 11.35 12.99 20.58 21.52

By plotting these results, using the diameters of the cylinders for abscissas and diameters of the shafts for ordinates, we find that for the long-stroke engines the results lie almost in a straight line expressed by the formula, diameter of shaft = .43  $\times$  diameter of cylinder; for the short-stroke engines the line is slightly curved, but does not diverge far from a straight line whose equation is, diameter of shaft = .4 diameter of cylinder. Using these two formulas, the diameters of the shafts will be 4.0, 4.3, 12.0, 12.9, 20.0, 21.5.

J. B. Stanwood, in *Engineering*, June 12, 1891, gives dimensions of shafts of Corliss engines in American practice for cylinders 10 to 30 in. diameter. The diameters range from  $4 \frac{15}{16}$  to  $14 \frac{15}{16}$ , following precisely the equation, diameter of shaft =  $\frac{1}{2}$  diameter of cylinder -  $\frac{1}{16}$  inch.

**Fly-wheel Shafts.**—Thus far we have considered the shaft as resisting the force of torsion and the bending moment produced by the pressure on the crank-pin. In the case of fly-wheel engines the shaft on the opposite side of the bearing from the crank-pin has to be designed with reference to the bending moment caused by the weight of the fly wheel, the weight of the shaft itself, and the strain of the belt. For engines in which there is an outboard bearing, the weight of fly-wheel and shaft being supported by two bearings, the point of the shaft at which the bending moment is a maximum may be taken as the point midway between the two bearings or at the middle of the fly-wheel hub, and the amount of the moment is the product of the weight supported by one of the bearings into the distance from the centre of that bearing to the middle point of the shaft. The shaft is thus to be treated as a beam supported at the ends and loaded in the middle. In the case of an overhung fly-wheel, the shaft having only one bearing, the point of maximum moment should be taken as the middle of the bearing, and its amount is very nearly the product of half the weight of the fly-wheel and the shaft into the distance from the middle of its hub from the middle of the bearing. The bending moment should be calculated and combined with the twisting moment as above shown, to obtain the equivalent twisting moment, and the diameter necessary at the point of maximum moment calculated therefrom.

In the case of our six engines we assume that the weights of the fly-wheels, together with the shaft, are double the weight of fly-wheel rim obtained from the formula,  $W = 785.40^n \frac{d^2 s}{D^2 T_1^2}$  (given under Fly-wheels);

that the shaft is supported by an outboard bearing, the distance between the two bearings being  $2\frac{1}{2}$ , 5, and 10 feet for the 10-in., 30-in., and 50-in. engines, respectively. The diameters of the fly-wheels are taken such that their rim velocity will be a little less than 6000 feet per minute.

Engine No.....	1	2	3	4	5	6
Diam. of cyl., inches.....	10	10	30	30	50	50
Diam. of fly-wheel, ft.....	7.5	15	14.5	29	21	42
Revs. per min .....	250	125	130	65	90	45
Half wt. fly-wh'l and shaft, lb.	268	536	5,968	11,936	26,384	52,769
Lever arm for max. mom., in.	15	15	30	30	60	60
Max. bending moment, in.-lb.	4020	8040	179,040	358,080	1,583,070	3,166,140

As these are very much less than the bending moments calculated from the pressures on the crank-pin, the diameters already found are sufficient for the diameter of the shaft at the fly-wheel hub.

In the case of engines with heavy band fly-wheels and with long fly-wheel shafts it is of the utmost importance to calculate the diameter of the shaft with reference to the bending moment due to the weight of the fly-wheel and the shaft.

B. H. Coffey (*Power*, October, 1892) gives the formula for combined bending and twisting resistance,  $T_1 = .196d^3S$ , in which  $T_1 = B + \sqrt{B^2 + T^2}$ ;  $T$  being the maximum, not the mean twisting moment; and finds empirical working values for  $.196S$  as below. He says: Four points should be considered in determining this value: First, the nature of the material; second, the manner of applying the loads, with shock or otherwise; third, the ratio of the bending moment to the torsional moment—the bending moment in a revolving shaft produces reversed strains in the material, which tend to rupture it; fourth, the size of the section. Inch for inch, large sections are weaker than small ones. He puts the dividing line between large and small sections at 10 in. diameter, and gives the following safe values of  $S \times .196$  for steel, wrought iron, and cast iron, for these conditions.

VALUE OF  $S \times .196$ .

Ratio.	Heavy Shafts with Shock.			Light shafts with Shock. Heavy Shafts No Shock.			Light Shafts No Shock.		
	Steel.	Wro't Iron.	Cast Iron.	Steel.	Wro't Iron.	Cast Iron.	Steel.	Wro't Iron.	Cast Iron.
$B$ to $T$ .									
3 to 10 or less.....	1045	880	440	1566	1320	660	2090	1760	880
3 to 5 or less.....	941	785	393	1410	1179	589	1882	1570	785
1 to 1 or less.....	855	715	358	1281	1074	537	1710	1430	715
$B$ greater than $T$ ..	784	655	328	1176	984	492	1568	1310	655

Mr. Coffey gives as an example of improper dimensions the fly-wheel shaft of a 1500 H.P. engine at Willimantic, Conn., which broke while the engine was running at 425 H.P. The shaft was 17 ft. 5 in. long between centres of bearings, 18 in. diam. for 8 ft. in the middle, and 15 in. diam. for the remainder, including the bearings. It broke at the base of the fillet connecting the two large diameters, or  $56\frac{1}{2}$  in. from the centre of the bearing. He calculates the mean torsional moment to be 446,654 inch-pounds, and the maximum at twice the mean; and the total weight on one bearing at 87,530 lbs., which, multiplied by  $56\frac{1}{2}$  in., gives 4,945,445 in.-lbs. bending moment at the fillet. Applying the formula  $T_1 = B + \sqrt{B^2 + T^2}$ , gives for equivalent twisting moment 9,971,045 in.-lbs. Substituting this value in the formula  $T_1 = .196, Sd^3$  gives for  $S$  the shearing strain 15,070 lbs. per sq. in., or if the metal had a shearing strength of 45,000 lbs., a factor of safety of only 3. Mr. Coffey considers that 6000 lbs. is all that should be allowed for  $S$  under these circumstances. This would give  $d = 20.35$  in. If we take from Mr. Coffey's table a value of  $.196S = 1100$ , we obtain  $d^3 = 9000$  nearly, or  $d = 20.8$  in., instead of 15 in., the actual diameter.

**Length of Shaft-bearings.**—There is as great a difference of opinion among writers, and as great a variation in practice concerning length of journal-bearings, as there is concerning crank-pins. The length of a

journal being determined from considerations of its heating, the observations concerning heating of crank-pins apply also to shaft-bearings, and the formulæ for length of crank-pins to avoid heating may also be used, using for the total load upon the bearing the resultant of all the pressures brought upon it, by the pressure on the crank, by the weight of the fly-wheel, and by the pull of the belt. After determining this pressure, however, we must resort to empirical values for the so-called constants of the formulæ, really variables, which depend on the power of the bearing to carry away heat, and upon the quantity of heat generated, which latter depends on the pressure, on the number of square feet of rubbing surface passed over in a minute, and upon the coefficient of friction. This coefficient is an exceedingly variable quantity, ranging from .01 or less with perfectly polished journals, having end-play, and lubricated by a pad or oil-bath, to .10 or more with ordinary oil-cup lubrication.

For shafts resisting torsion only, Marks gives for length of bearing  $l = .0000247fpND^2$ , in which  $f$  is the coefficient of friction,  $p$  the mean pressure in pounds per square inch on the piston,  $N$  the number of single strokes per minute, and  $D$  the diameter of the piston. For shafts under the combined stress due to pressure on the crank-pin, weight of fly-wheel, etc., he gives the following: Let  $Q$  = reaction at bearing due to weight,  $S$  = stress due steam pressure on piston, and  $R_1$  = the resultant force; for horizontal engines,  $R_1 = \sqrt{Q^2 + S^2}$ , for vertical engines  $R_1 = Q + S$ , when the pressure on the crank is in the same direction as the pressure of the shaft on its bearings, and  $R_1 = Q - S$  when the steam pressure tends to lift the shaft from its bearings. Using empirical values for the work of friction per square inch of projected area, taken from dimensions of crank-pins in marine vessels, he finds the formula for length of shaft-journals  $l = .0000325fR_1N$ , and recommends that to cover the defects of workmanship, neglect of oiling, and the introduction of dust,  $f$  be taken at .16 or even greater. He says that 500 lbs. per sq. in. of projected area may be allowed for steel or wrought-iron shafts in brass bearings with good results if a less pressure is not attainable without inconvenience. Marks says that the use of empirical rules that do not take account of the number of turns per minute has resulted in bearings much too long for slow-speed engines and too short for high-speed engines.

Whitham gives the same formula, with the coefficient .00002575.

Thurston says that the maximum allowable mean intensity of pressure may be, for all cases, computed by his formula for journals,  $l = \frac{PV}{60,000d}$ , or

by Rankine's,  $l = \frac{P(V + 20)}{44,800d}$ , in which  $P$  is the mean total pressure in pounds,

$V$  the velocity of rubbing surface in feet per minute, and  $d$  the diameter of the shaft in inches. It must be borne in mind, he says, that the friction work on the main bearing next the crank is the sum of that due the action of the piston on the pin, and that due that portion of the weight of wheel and shaft and of pull of the belt which is carried there. The outboard bearing carries practically only the latter two parts of the total. The crank-shaft journals will be made longer on one side, and perhaps shorter on the other, than that of the crank-pin, in proportion to the work falling upon each, i.e., to their respective products of mean total pressure, speed of rubbing surfaces, and coefficients of friction.

Unwin says: Journals running at 150 revolutions per minute are often only one diameter long. Fan shafts running 150 revolutions per minute have journals six or eight diameters long. The ordinary empirical mode of proportioning the length of journals is to make the length proportional to the diameter, and to make the ratio of length to diameter increase with the speed. For wrought-iron journals:

Revs. per min. =	50	100	150	200	250	500	1000	$\frac{l}{d} = .004R + 1.$
Length ÷ diam. =	1.2	1.4	1.6	1.8	2.0	3.0	5.0.	

Cast-iron journals may have  $l \div d = 9/10$ , and steel journals  $l \div d = 1\frac{1}{4}$ , of the above values.

Unwin gives the following, calculated from the formula  $l = \frac{0.4 \text{ H.P.}}{r}$ , in which  $r$  is the crank radius in inches, and H.P. the horse-power transmitted to the crank-pin.

THEORETICAL JOURNAL LENGTH IN INCHES.

Load on Journal in pounds.	Revolutions of Journal per minute.					
	50	100	200	300	500	1000
1,000	.2	.4	.8	1.2	2.	4.

30,000	6.	12.	24.	36.	....	....
40,000	8.	16.	32.	....	....	....
50,000	10.	20.	40.	....	....	....

Applying these different formulæ to our six engines, we have:

Engine No.....	1	2	3	4	5	6
Diam. cyl.....	10	10	30	30	50	50
Horse-power.....	50	50	450	450	1,250	1,250
Revs. per min.....	250	125	130	65	90	45
Mean pressure on crank-pin = <i>S</i> .....	3,299	3,299	23,185	23,185	58,905	58,905
Half wt. of fly-wheel and shaft = <i>Q</i> ..	268	536	5,968	11,936	26,470	52,940
Resultant press. on bearing $\sqrt{Q^2 + S^2} = R_1$ ..	3,310	3,335	23,924	26,194	64,580	79,200
Diam. of shaft journal.....	3.84	4.39	11.35	12.99	20.58	21.52
Length of shaft journal:						
Marks, $l = .0000325fR_1N(f=.10)$	5.38	2.71	20.87	11.07	37.78	23.17
Whitham, $l = .0000515fR_1R(f=10)$	4.27	2.15	16.53	8.77	29.95	18.35
Thurston, $l = \frac{PV}{60,000d}$ .....	3.61	1.82	14.00	7.43	25.36	15.55
Rankine, $l = \frac{P(V+20)}{44,800d}$ .....	5.22	2.78	21.70	10.85	35.16	22.47
Unwin, $l = (.004R + 1)d$ .....	7.68	6.59	17.25	16.36	27.99	25.39
Unwin, $l = \frac{0.4 \text{ H.P.}}{r}$ .....	3.33	1.60	12.00	6.00	20.83	10.42
Average.....	4.92	2.99	17.05	10.00	29.54	19.22

If we divide the mean resultant pressure on the bearing by the projected area, that is, by the product of the diameter and length of the journal, using the greatest and smallest length out of the seven lengths for each journal given above, we obtain the pressure per square inch upon the bearing, as follows:

Engine No .....	1	2	3	4	5	6
Pressure per sq. in., shortest journal.	259	455	176	336	151	353
Longest journal.....	112	115	97	123	83	145
Average journal.....	175	254	124	202	106	191
Journal of length = diam.....	.....	173	.....	155	.....	175

Many of the formulæ give for the long-stroke engines a length of journal less than the diameter, but such short journals are rarely used in practice. The last line in the above table has been calculated on the supposition that

the journals of the long-stroke engines are made of a length equal to the diameter.

In the dimensions of Corliss engines given by J. B. Stanwood (*Eng.*, June 12, 1891), the lengths of the journals for engines of diam. of cyl. 10 to 20 in. are the same as the diam. of the cylinder, and a little more than twice the diam. of the journal. For engines above 20 in. diam. of cyl. the ratio of length to diam. is decreased so that an engine of 30 in. diam. has a journal 26 in. long, its diameter being  $14\frac{5}{8}$  in. These lengths of journal are greater than those given by any of the formulæ above quoted.

There thus appears to be a hopeless confusion in the various formulæ for length of shaft journals, but this is no more than is to be expected from the variation in the coefficient of friction, and in the heat-conducting power of journals in actual use, the coefficient varying from .10 (or even .16 as given by Marks) down to .01, according to the condition of the bearing surfaces

and the efficiency of lubrication. Thurston's formula,  $l = \frac{PV}{60,000d}$ , reduces to the form  $l = .000004363PR$ , in which  $P$  = mean total load on journal, and  $R$  = revolutions per minute. This is of the same form as Marks' and Whitham's formulæ, in which, if  $f$  the coefficient of friction be taken at .10, the coefficients of  $PR$  are, respectively, .0000065 and .00000515. Taking the mean of these three formulæ, we have  $l = .0000053PR$ , if  $f = .10$  or  $l = .000053fPR$  for any other value of  $f$ . The author believes this to be as safe a formula as any for length of journals, with the limitation that if it brings a result of length of journal less than the diameter, then the length should be made equal to the diameter. Whenever with  $f = .10$  it gives a length which is inconvenient or impossible of construction on account of limited space, then provision should be made to reduce the value of the coefficient of friction below .10 by means of forced lubrication, end play, etc., and to carry away the heat, as by water-cooled journal-boxes. The value of  $P$  should be taken as the resultant of the mean pressure on the crank, and the load brought on the bearing by the weight of the shaft, fly-wheel, etc., as calculated by the formula already given, viz.,  $R_1 = \sqrt{Q^2 + S^2}$  for horizontal engines, and  $R_1 = Q + S$  for vertical engines.

For our six engines the formula  $l = .0000053PR$  gives, with the limitation for the long-stroke engines that the length shall not be less than the diameter, the following:

Engine No.....	1	2	3	4	5	6
Length of journal.....	4.39	4.39	16.48	12.99	30.80	21.52
Pressure per square inch on journal..	196	173	128	155	102	171

**Crank-shafts with Centre-crank and Double-crank Arms.**—In centre-crank engines, one of the crank-arms, and its adjoining journal, called the after journal, usually transmit the power of the engine to the work to be done, and the journal resists both twisting and bending moments, while the other journal is subjected to bending moment only.

For the after crank-journal the diameter should be calculated the same as for an overhung crank, using the formula for combined bending and twisting moment,  $T_1 = B + \sqrt{B^2 + T^2}$ , in which  $T_1$  is the equivalent twisting moment,  $B$  the bending moment, and  $T$  the twisting moment. This value

of  $T_1$  is to be used in the formula diameter =  $\sqrt[3]{\frac{5.1T}{S}}$ . The bending mo-

ment is taken as the maximum load on piston multiplied by one fourth of the length of the crank-shaft between middle points of the two journal bearings, if the centre crank is midway between the bearings, or by one half the distance measured parallel to the shaft from the middle of the crank-pin to the middle of the after bearing. This supposes the crank-shaft to be a beam loaded at its middle and supported at the ends, but Whitham would make the bending moment only one half of this, considering the shaft to be a beam secured or fixed at the ends, with a point of contraflexure one fourth of the length from the end. The first supposition is the safer, but since the bending moment will in any case be much less than the twisting moment, the resulting diameter will be but little greater than if Whitham's supposition is used. For the forward journal, which is sub-

jected to bending moment only, diameter of shaft =  $\sqrt[3]{\frac{10.2B}{S}}$ , in which  $B$

is the maximum bending moment and  $S$  the safe shearing strength of the metal per square inch.

For our six engines, assuming them to be centre-crank engines, and considering the crank-shaft to be a beam supported at the ends and loaded in the middle, and assuming lengths between centres of shaft bearings as given below, we have:

Engine No.....	1	2	3	4	5	6
Length of shaft, assumed, inches, $L$ .....	20	24	48	60	76	96
Max. press. on crank-pin, $P$	7,854	7,854	70,686	70,686	196,350	196,350
Max. bending moment, $B = \frac{1}{4}PL$ , inch-lbs.....	39,270	49,637	848,232	1,060,290	3,729,750	4,712,400
Twisting moment, $T$ .....	47,124	94,248	1,060,290	2,120,580	4,712,400	9,424,800
Equiv. twisting moment, $B + \sqrt{B^2 + T^2}$ .....	101,000	156,000	2,208,000	3,430,000	9,740,000	15,240,000
Diameter of after journal, $d = \sqrt[3]{\frac{5.1T_1}{8000}}$ .....	3.98	4.60	11.15	13.00	18.25	21.20
Diam. of forward journal, $d_1 = \sqrt[3]{\frac{10.2B}{8000}}$ .....	3.68	3.99	10.28	11.16	16.82	18.18

The lengths of the journals would be calculated in the same manner as in the case of overhung cranks, by the formula  $l = .000053fPR$ , in which  $P$  is the resultant of the mean pressure due to pressure of steam on the piston, and the load of the fly-wheel, shaft, etc., on each of the two bearings. Unless the pressures are equally divided between the two bearings, the calculated lengths of the two will be different; but it is usually customary to make them both of the same length, and in no case to make the length less than the diameter. The diameters also are usually made alike for the two journals, using the largest diameter found by calculation.

The crank-pin for a centre crank should be of the same length as for an overhung crank, since the length is determined from considerations of heating, and not of strength. The diameter also will usually be the same, since it is made great enough to make the pressure per square inch on the projected area (product of length by diameter) small enough to allow of free lubrication, and the diameter so calculated will be greater than is required for strength.

**Crank-shaft with Two Cranks coupled at 90°.**—If the whole power of the engine is transmitted through the after journal of the after crank-shaft, the greatest twisting moment is equal to 1.414 times the maximum twisting moment due to the pressure on one of the crank-pins. If  $T$  = the maximum twisting moment produced by the steam-pressure on one of the pistons, then  $T_1$  the maximum twisting moment on the after part of the crank-shaft, and on the line-shaft, produced when each crank makes an angle of 45° with the centre line of the engine, is  $1.414T$ . Substituting this value in the formula for diameter to resist simple torsion, viz.,  $d = \sqrt[3]{\frac{5.1T}{S}}$ , we have  $d = \sqrt[3]{\frac{5.1 \times 1.414T}{S}}$ , or  $d = 1.932 \sqrt[3]{\frac{T}{S}}$ , in which  $T$  is

the maximum twisting moment produced by one of the pistons,  $d$  = diameter in inches, and  $S$  = safe working shearing strength of the material. For the forward journal of the after crank, and the after journal of the forward crank, the torsional moment is that due to the pressure of steam on the forward piston only, and for the forward journal of the forward crank, if none of the power of the engine is transmitted through it, the torsional moment is zero, and its diameter is to be calculated for bending moment only.

**For Combined Torsion and Flexure.**—Let  $B_1$  = bending moment on either journal of the forward crank due to maximum pressure on

forward piston,  $B_2$  = bending moment on either journal of the after crank due to maximum pressure on after piston,  $T_1$  = maximum twisting moment on after journal of forward crank, and  $T_2$  = maximum twisting moment on after journal of after crank due to pressure on the after piston.

Then equivalent twisting moment on after journal of forward crank =  $B_2 + \sqrt{B_1^2 + T_1^2}$ .

On forward journal of after crank =  $B_2 + \sqrt{B_2^2 + T_1^2}$ .

On after journal of after crank =  $B_2 + \sqrt{B_2^2 + (T_1 + T_2)^2}$ .

These values of equivalent twisting moment are to be used in the formula for diameter of journals  $d = \sqrt[3]{\frac{5.1T}{S}}$ . For the forward journal of the

forward crank-shaft  $d = \sqrt[3]{\frac{10.2B_1}{S}}$ .

It is customary to make the two journals of the forward crank of one diameter, viz., that calculated for the after journal.

**For a Three-cylinder Engine** with cranks at 120°, the greatest twisting moment on the after part of the shaft, if the maximum pressures on the three pistons are equal, is equal to twice the maximum pressure on any one piston, and it takes place when two of the cranks make angles of 30° with the centre line, the third crank being at right angles to it. (For demonstration, see Whitham's "Steam-engine Design," p. 252.) For combined torsion and flexure the same method as above given for two crank engines is adopted for the first two cranks; and for the third, or after crank, if all the power of the three cylinders is transmitted through it, we have the equivalent twisting moment on the forward journal =  $B_3 + \sqrt{B_3^2 + (T_1 + T_2)^2}$ , and on the after journal =  $B_3 + \sqrt{B_3^2 + (T_1 + T_2 + T_3)^2}$ ,  $B_3$  and  $T_3$  being respectively the bending and twisting moments due to the pressure on the third piston.

**Crank-shafts for Triple-expansion Marine Engines**, according to an article in *The Engineer*, April 25, 1890, should be made larger than the formulæ would call for, in order to provide for the stresses due to the racing of the propeller in a sea-way, which can scarcely be calculated. A kind of unwritten law has sprung up for fixing the size of a crank-shaft, according to which the diameter of the shaft is made about 0.45D, where D is the diameter of the high-pressure cylinder. This is for solid shafts. When the speeds are high, as in war-ships, and the stroke short, the formula becomes 0.4D, even for hollow shafts.

**The Valve-stem or Valve-rod.**—The valve-rod should be designed to move the valve under the most unfavorable conditions, which are when the stem acts by thrusting, as a long column, when the valve is unbalanced (a balanced valve may become unbalanced by the joint leaking) and when it is imperfectly lubricated. The load on the valve is the product of the area into the greatest unbalanced pressure upon it per square inch, and the coefficient of friction may be as high as 20%. The product of this coefficient and the load is the force necessary to move the valve, which equals the maximum thrust on the valve-rod. From this force the diameter of the valve-rod may be calculated by Hodgkinson's formula for columns. An

empirical formula given by Seaton is: Diam. of rod =  $d = \sqrt{\frac{lbp}{F}}$ , in which

$l$  = length and  $b$  = breadth of valve, in inches;  $p$  = maximum absolute pressure on the valve in lbs. per sq. in., and  $F$  a coefficient whose values are, for iron: long rod 10,000, short 12,000; for steel: long rod 12,000, short 14,500.

Whitham gives the short empirical rule: Diam. of valve-rod = 1/30 diam. of cyl. =  $\frac{1}{3}$  diam. of piston-rod.

**Size of Slot-link.** (Seaton.)—Let  $D$  be the diam. of the valve rod

$$D = \sqrt{\frac{lbp}{12,000}}$$

then Diameter of block-pin when overhung	= $D$ .
“ “ “ secured at both ends	= $0.75 \times D$ .
“ eccentric-rod pins	= $0.7 \times D$ .
“ suspension-rod pins	= $0.55 \times D$ .
“ “ “ pin when overhung	= $0.75 \times D$ .

Breadth of link	= $0.8 \text{ to } 0.9 \times D.$
Length of block	= $1.8 \text{ to } 1.6 \times D.$
Thickness of bars of link at middle	= $0.7 \times D.$
If a single suspension rod of round section, its diameter	= $0.7 \times D.$
If two suspension rods of round section, their diameter	= $0.55 \times D.$

**Size of Double-bar Links.**—When the distance between centres of eccentric pins = 6 to 8 times throw of eccentrics (throw = eccentricity = half-travel of valve at full gear)  $D$  as before :

Depth of bars	= $1.25 \times D + \frac{3}{4} \text{ in.}$
Thickness of bars	= $0.5 \times D + \frac{1}{4} \text{ in.}$
Length of sliding-block	= $2.5 \text{ to } 3 \times D.$
Diameter of eccentric-rod pins	= $0.8 \times D + \frac{1}{4} \text{ in.}$
“ centre of sliding-block	= $1.3 \times D.$

When the distance between eccentric-rod pins = 5 to  $5\frac{1}{2}$  times throw of eccentrics:

Depth of bars	= $1.25 \times D + \frac{1}{2} \text{ in.}$
Thickness of bars	= $0.5 \times D + \frac{1}{4} \text{ in.}$
Length of sliding-block	= $2.5 \text{ to } 3 \times D.$
Diameter of eccentric-rod pins	= $0.75 \times D.$

Diameter of eccentric bolts (top end) at bottom of thread =  $0.42 \times D$  when of iron, and  $0.38 \times D$  when of steel.

**The Eccentric.**—Diam. of eccentric-sheave =  $2.4 \times$  throw of eccentric +  $1.2 \times$  diam. of shaft.  $D$  as before

Breadth of the sheave at the shaft.....	= $1.15 \times D + 0.65 \text{ inch}$
Breadth of the sheave at the strap.....	= $D + 0.6 \text{ inch.}$
Thickness of metal around the shaft .....	= $0.7 \times D + 0.5 \text{ inch.}$
Thickness of metal at circumference .....	= $0.6 \times D + 0.4 \text{ inch.}$
Breadth of key.....	= $0.7 \times D + 0.5 \text{ inch.}$
Thickness of key.....	= $0.25 \times D + 0.5 \text{ inch.}$
Diameter of bolts connecting parts of strap.....	= $0.6 \times D + 0.1 \text{ inch.}$

#### THICKNESS OF ECCENTRIC-STRAP.

When of bronze or malleable cast iron:

Thickness of eccentric-strap at the middle.....	= $0.4 \times D + 0.6 \text{ inch.}$
“ “ “ “ “ sides.....	= $0.3 \times D + 0.5 \text{ inch.}$

When of wrought iron or cast steel:

Thickness of eccentric-strap at the middle.....	= $0.4 \times D + 0.5 \text{ inch.}$
“ “ “ “ “ sides.....	= $0.27 \times D + 0.4 \text{ inch}$

**The Eccentric-rod.**—The diameter of the eccentric-rod in the body and at the eccentric end may be calculated in the same way as that of the connecting-rod, the length being taken from centre of strap to centre of pin. Diameter at the link end =  $0.8D + 0.2 \text{ inch.}$

This is for wrought-iron; no reduction in size should be made for steel.

Eccentric-rods are often made of rectangular section.

**Reversing-gear** should be so designed as to have more than sufficient strength to withstand the strain of both the valves and their gear at the same time under the most unfavorable circumstances; it will then have the stiffness requisite for good working.

Assuming the work done in reversing the link-motion,  $W$ , to be only that due to overcoming the friction of the valves themselves through their whole travel, then, if  $T$  be the travel of valves in inches; for a compound engine

$$W = \frac{T}{12} \left( \frac{l \times b \times p}{5} \right) + \frac{T}{12} \left( \frac{l^1 \times b^1 \times p^1}{5} \right);$$

$l^1$ ,  $b^1$  and  $p^1$  being length, breadth and maximum steam-pressure on valve of the second cylinder; and for an expansive engine

$$W = 2 \times \frac{T}{12} \left( \frac{l \times b \times p}{5} \right); \text{ or } \frac{T}{30} (l \times b \times p).$$

To provide for the friction of link-motion, eccentrics and other gear, and for abnormal conditions of the same, take the work at one and a half times the above amount.

To find the strain at any part of the gear having motion when reversing, divide the work so found by the space moved through by that part in feet; the quotient is the strain in pounds; and the size may be found from the ordinary rules of construction for any of the parts of the gear. (Seaton.)

**Engine-frames or Bed-plates.**—No definite rules for the design of engine-frames have been given by authors of works on the steam-engine. The proportions are left to the designer who uses "rule of thumb," or copies from existing engines. F. A. Halsey (*Am. Mach.*, Feb. 14, 1895) has made a comparison of proportions of the frames of horizontal Corliss engines of several builders. The method of comparison is to compute from the measurements the number of square inches in the smallest cross-section of the frame, that is, immediately behind the pillow-block, also to compute the total maximum pressure upon the piston, and to divide the latter quantity by the former. The result gives the number of pounds pressure upon the piston allowed for each square inch of metal in the frame. He finds that the number of pounds per square inch of smallest section of frame ranges from 217 for a 10 × 30-in. engine up to 575 for a 28 × 48-inch. A 30 × 60-inch engine shows 350 lbs., and a 32-inch engine which has been running for many years shows 667 lbs. Generally the strains increase with the size of the engine, and more cross-section of metal is allowed with relatively long strokes than with short ones.

From the above Mr. Halsey formulates the general rule that in engines of moderate speed, and having strokes up to one and one-half times the diameter of the cylinder, the load per square inch of smallest section should be for a 10-inch engine 300 pounds, which figure should be increased for larger bores up to 500 pounds for a 30-inch cylinder of same relative stroke. For high speeds or for longer strokes the load per square inch should be reduced.

### FLY-WHEELS.

The function of a fly-wheel is to store up and to restore the periodical fluctuations of energy given to or taken from an engine or machine, and thus to keep approximately constant the velocity of rotation. Rankine calls the quantity  $\frac{\Delta E}{2E_0}$  the coefficient of fluctuation of speed or of unsteadiness, in

which  $E_0$  is the mean actual energy, and  $\Delta E$  the excess of energy received or of work performed, above the mean, during a given interval. The ratio of the periodical excess or deficiency of energy  $\Delta E$  to the whole energy exerted in one period or revolution General Morin found to be from  $\frac{1}{6}$  to  $\frac{1}{4}$  for single-cylinder engines using expansion; the shorter the cut-off the higher the value. For a pair of engines with cranks coupled at 90° the value of the ratio is about  $\frac{1}{4}$ , and for three engines with cranks at 120°,  $\frac{1}{12}$  of its value for single-cylinder engines. For tools working at intervals, such as punching, slotting and plate-cutting machines, coining-presses, etc.,  $\Delta E$  is nearly equal to the whole work performed at each operation.

A fly-wheel reduces the coefficient  $\frac{\Delta E}{2E_0}$  to a certain fixed amount, being about  $\frac{1}{32}$  for ordinary machinery, and  $\frac{1}{50}$  or  $\frac{1}{60}$  for machinery for fine purposes.

If  $m$  be the reciprocal of the intended value of the coefficient of fluctuation of speed,  $\Delta E$  the fluctuation or energy,  $I$  the moment of inertia of the fly-wheel alone, and  $a_0$  its mean angular velocity,  $I = \frac{mg\Delta E}{a_0^2}$ . As the rim of a fly-wheel is usually heavy in comparison with the arms,  $I$  may be taken to equal  $Wr^2$ , in which  $W$  = weight of rim in pounds, and  $r$  the radius of the wheel; then  $W = \frac{mg\Delta E}{a_0^2 r^2} = \frac{mg\Delta E}{v^2}$ , if  $v$  be the velocity of the rim in feet per second. The usual mean radius of the fly-wheel in steam-engines is from three to five times the length of the crank. The ordinary values of the product  $mg$ , the unit of time being the second, lie between 1000 and 2000 feet. (Abridged from Rankine, *S. E.*, p. 62.)

Thurston gives for engines with automatic valve-gear  $W = 250,004 \frac{ASp}{R^2 D^2}$ , in which  $A$  = area of piston in square inches,  $S$  = stroke in feet,  $p$  = mean steam-pressure in lbs. per sq. in.,  $R$  = revolutions per minute,  $D$  = outside diameter of wheel in feet. Thurston also gives for ordinary forms of

non-condensing engine with a ratio of expansion between 3 and 5,  $W = \frac{aAS}{R^2D^2}$ , in which  $a$  ranges from 10,000,000 to 15,000,000, averaging 12,000,000. For gas-engines, in which the charge is fired with every revolution, the *American Machinist* gives this latter formula, with  $a$  doubled, or 24,000,000. Presumably, if the charge is fired every other revolution,  $a$  should be again doubled.

Rankine ("Useful Rules and Tables," p. 247) gives  $W = 475,000 \frac{ASp}{VD^2R^2}$ , in which  $V$  is the variation of speed per cent. of the mean speed. Thurston's first rule above given corresponds with this if we take  $V$  at 1.9 per cent.

Hartnell (Proc. Inst., M. E. 1882, 427) says: The value of  $V$ , or the variation permissible in portable engines, should not exceed 3 per cent. with an ordinary load, and 4 per cent. when heavily loaded. In fixed engines, for ordinary purposes,  $V = 2\frac{1}{2}$  to 3 per cent. For good governing or special purposes, such as cotton-spinning, the variation should not exceed  $1\frac{1}{2}$  to 2 per cent.

F. M. Rites (Trans. A. S. M. E., xiv. 100) develops a new formula for weight of rim, viz.,  $W = \frac{C \times \text{I.H.P.}}{R^3D^2}$ , and weight of rim per horse-power =  $\frac{C}{R^3D^2}$ , in which  $C$  varies from 10,000,000,000 to 20,000,000,000; also using the latter value of  $C$ , he obtains for the energy of the fly-wheel  $\frac{Mv^2}{2} = \frac{W}{64.4} \frac{3.14^2 D^2 R^2}{3600} = \frac{C \times \text{H.P.} (3.14)^2 D^2 R^2}{R^3 D^2 \times 64.4 \times 3600} = \frac{850,000 \text{ H.P.}}{R}$ . Fly-wheel energy per H.P. =  $\frac{850,000}{R}$ .

The limit of variation of speed with such a weight of wheel from excess of power per fraction of revolution is less than .0023.

The value of the constant  $C$  given by Mr. Rites was derived from practice of the Westinghouse single-acting engines used for electric-lighting. For double-acting engines in ordinary service a value of  $C = 5,000,000,000$  would probably be ample.

From these formulæ it appears that the weight of the fly-wheel for a given horse-power should vary inversely with the cube of the revolutions and the square of the diameter.

J. B. Stanwood (*Eng'g*, June 12, 1891) says: Whenever 480 feet is the lowest piston-speed probable for an engine of a certain size, the fly-wheel weight for that speed approximates closely to the formula

$$W = 700,000 \frac{d^2s}{D^2R^2}.$$

$W$  = weight in pounds,  $d$  = diameter of cylinder in inches,  $s$  = stroke in inches,  $D$  = diameter of wheel in feet,  $R$  = revolutions per minute, corresponding to 480 feet piston-speed.

In a Ready Reference Book published by Mr. Stanwood, Cincinnati, 1892, he gives the same formula, with coefficients as follows: For slide-valve engines, ordinary duty, 350,000; same, electric-lighting, 700,000; for automatic high-speed engines, 1,000,000; for Corliss engines, ordinary duty 700,000, electric-lighting 1,000,000.

Thurston's formula above given,  $W = \frac{aAS}{R^2D^2}$ , with  $a = 12,000,000$ , when reduced to terms of  $d$  and  $s$  in inches, becomes  $W = 785,400 \frac{d^2s}{R^2D^2}$ .

If we reduce it to terms of horse-power, we have  $\text{I.H.P.} = \frac{2ASPR}{33,000}$ , in which  $P$  = mean effective pressure. Taking this at 40 lbs., we obtain  $W = 5,000,000,000 \frac{\text{I.H.P.}}{R^3D^2}$ . If mean effective pressure = 30 lbs., then  $W = 6,666,000,000 \frac{\text{I.H.P.}}{R^3D^2}$ .

Emil Theiss (*Am. Mach.*, Sept. 7 and 14, 1893) gives the following values of  $d$ , the coefficient of steadiness, which is the reciprocal of what Rankine calls the coefficient of fluctuation:

For engines operating--

Hammering and crushing machinery.....	$d = 5$
Pumping and shearing machinery.....	$d = 20$ to $30$
Weaving and paper-making machinery.....	$d = 40$
Milling machinery.....	$d = 50$
Spinning machinery.....	$d = 50$ to $100$
Ordinary driving-engines (mounted on bed-plate), belt transmission.....	$d = 35$
Gear-wheel transmission.....	$d = 50$

Mr. Theiss's formula for weight of fly-wheel in pounds is  $W = i \times \frac{d \times \text{I.H.P.}}{V^2 \times n}$ , where  $d$  is the coefficient of steadiness,  $V$  the mean velocity of the fly-wheel rim in feet per second,  $n$  the number of revolutions per minute,  $i$  is a coefficient obtained by graphical solution, the values of which for different conditions are given in the following table. In the lines under "cut-off,"  $p$  means "compression to initial pressure," and  $O$  "no compression":

800	30,190	31,570	35,140	33,810	36,470	32,850	33,810	32,370

As a mean value of  $i$  for these engines we may use 33,810.

**Centrifugal Force in Fly-wheels.**—Let  $W$  = weight of rim in pounds;  $R$  = mean radius of rim in feet;  $r$  = revolutions per minute,  $g = 32.16$ ;  $v$  = velocity of rim in feet per second =  $2\pi Rr \div 60$ .

$$\text{Centrifugal force of whole rim} = F = \frac{Wv^2}{gR} = \frac{4W\pi^2 Rr^2}{3600g} = .000341WRr^2.$$

The resultant, acting at right angles to a diameter of half of this force, tends to disrupt one half of the wheel from the other half, and is resisted by the section of the rim at each end of the diameter. The resultant of half the radial forces taken at right angles to the diameter is  $1 \div \frac{1}{2}\pi = \frac{2}{\pi}$  of the sum of these forces; hence the total force  $F$  is to be divided by  $2 \times 2 \times 1.5708 = 6.2832$  to obtain the tensile strain on the cross-section of the rim, or, total strain on the cross-section =  $S = .00005427WRr^2$ . The weight  $W_1$  of a rim of cast iron 1 inch square in section is  $2\pi R \times 3.125 = 19.635R$  pounds, whence strain per square inch of sectional area of rim =  $S_1 = \frac{S}{W_1} = .0010656R^2r^2 = .0002664D^2r^2 = .0000270V^2$ , in which  $D$  = diameter of wheel in feet, and  $V$  is velocity of rim in feet per minute.  $S_1 = .0972v^2$ , if  $v$  is taken in feet per second.

For wrought iron.....  $S_1 = .0011366R^2r^2 = .0002842D^2r^2 = .0000288V^2$ .  
 For steel.....  $S_1 = .0011593R^2r^2 = .0002901D^2r^2 = .0000294V^2$ .  
 For wood.....  $S_1 = .0000888R^2r^2 = .0000222D^2r^2 = .00000225V^2$ .

The specific gravity of the wood being taken at  $0.6 = 37.5$  lbs. per cu. ft., or  $1/12$  the weight of cast iron.

*Example.*—Required the strain per square inch in the rim of a cast-iron wheel 30 ft. diameter, 60 revolutions per minute.

*Answer.*  $15^2 \times 60^2 \times .0010656 = 863.1$  lbs.

Required the strain per square inch in a cast-iron wheel-rim running a mile a minute. *Answer.*  $.000027 \times 5280^2 = 752.7$  lbs.

In cast-iron fly-wheel rims, on account of their thickness, there is difficulty in securing soundness, and a tensile strength of 10,000 lbs. per sq. in. is as much as can be assumed with safety. Using a factor of safety of 10 gives a maximum allowable strain in the rim of 1000 lbs. per sq. in., which corresponds to a rim velocity of 6085 ft. per minute.

For any given material, as cast iron, the strength to resist centrifugal force depends only on the velocity of the rim, and not upon its bulk or weight.

Chas. E. Emery (*Cass. Mag.*, 1892) says: By calculation half the strength of the arms is available to strengthen the rim, or a trifle more if the fly-wheel centres are relatively large. The arms, however, are subject to transverse strains, from belts and from changes of speed, and there is, moreover, no certainty that the arms and rim will be adjusted so as to pull exactly together in resisting disruption, so the plan of considering the rim by itself and making it strong enough to resist disruption by centrifugal force within safe limits, as is assumed in the calculations above, is the safer way.

It does not appear that fly-wheels of customary construction should be unsafe at the comparatively low speeds now in common use if proper materials are used in construction. The cause of rupture of fly-wheels that have failed is usually either the "running away" of the engine, such as may be caused by the breaking or slackness of a governor-belt, or incorrect design or defective materials of the fly-wheel.

Chas. T. Porter (*Trans. A. S. M. E.*, xiv. 808) states that no case of the bursting of a fly-wheel with a solid rim in a high-speed engine is known. He attributes the bursting of wheels built in segments to insufficient strength of the flanges and bolts by which the segments are held together. (See also Thurston, "Manual of the Steam-engine," Part II, page 413, etc.)

**Arms of Fly-wheels and Pulleys.**—Professor Torrey (*Am. Mach.*, July 30, 1891) gives the following formula for arms of elliptical cross-section of cast-iron wheels:

$W$  = load in pounds acting on one arm;  $S$  = strain on belt in pounds per inch of width, taken at 56 for single and 112 for double belts;  $v$  = width of belt in inches;  $n$  = number of arms;  $L$  = length of arm in feet;  $b$  = breadth of arm at hub;  $d$  = depth of arm at hub, both in inches:  $W = \frac{Sv}{n}$ ,

$b = \frac{WL}{30d^2}$ . The breadth of the arm is its least dimension = minor axis of the ellipse, and the depth the major axis. This formula is based on a factor of safety of 10.

In using the formula, first assume some depth for the arm, and calculate the required breadth to go with it. If it gives too round an arm, assume the depth a little greater, and repeat the calculation. A second trial will almost always give a good section.

The size of the arms at the hub having been calculated, they may be somewhat reduced at the rim end. The actual amount cannot be calculated, as there are too many unknown quantities. However, the depth and breadth can be reduced about one third at the rim without danger, and this will give a well-shaped arm.

Pulleys are often cast in halves, and bolted together. When this is done the greatest care should be taken to provide sufficient metal in the bolts. This is apt to be the very weakest point in such pulleys. The combined area of the bolts at each joint should be about 28/100 the cross-section of the pulley at that point. (Torrey.)

Unwin gives 
$$d = 0.6337 \sqrt[3]{\frac{BD}{n}}$$
 for single belts ;

$$d = 0.798 \sqrt[3]{\frac{BD}{n}}$$
 for double belts;

$D$  being the diameter of the pulley, and  $B$  the breadth of the rim, both in inches. These formulæ are based on an elliptical section of arm in which  $b = 0.4d$  or  $d = 2.5b$  on a width of belt = 4/5 the width of the pulley rim, a maximum driving force transmitted by the belt of 56 lbs. per inch of width for a single belt and 112 lbs. for a double belt, and a safe working stress of cast iron of 2250 lbs. per square inch.

If in Torrey's formula we make  $b = 0.4d$ , it reduces to

$$b = \sqrt[3]{\frac{WL}{187.5}}; \quad d = \sqrt[3]{\frac{WL}{12}}.$$

*Example.*—Given a pulley 10 feet diameter; 8 arms, each 4 feet long; face, 36 inches wide; belt, 30 inches: required the breath and depth of the arm at the hub. According to Unwin,

$$d = 0.6337 \sqrt[3]{\frac{BD}{n}} = 0.6337 \sqrt[3]{\frac{36 \times 120}{8}} = 5.16 \text{ for single belt, } b = 2.06;$$

$$d = 0.798 \sqrt[3]{\frac{BD}{n}} = 0.798 \sqrt[3]{\frac{36 \times 120}{8}} = 6.50 \text{ for double belt, } b = 2.60.$$

According to Torrey, if we take the formula  $b = \frac{WL}{30d^2}$  and assume  $d = 5$  and 6.5 inches, respectively, for single and double belts, we obtain  $b = 1.08$  and 1.33, respectively, or practically only one half of the breadth according to Unwin, and, since transverse strength is proportional to breadth, an arm only one half as strong.

Torrey's formula is said to be based on a factor of safety of 10, but this factor can be only apparent and not real, since the assumption that the strain on each arm is equal to the strain on the belt divided by the number of arms, is, to say the least, inaccurate. It would be more nearly correct to say that the strain of the belt is divided among half the number of arms. Unwin makes the same assumption in developing his formula, but says it is only in a rough sense true, and that a large factor of safety must be allowed. He therefore takes the low figure of 2250 lbs. per square inch for the safe working strength of cast iron. Unwin says that his equations agree well with practice.

**Diameters of Fly-wheels for Various Speeds.**—If 6000 feet per minute be the maximum velocity of rim allowable, then  $6000 = \pi R D$ , in which  $R$  = revolutions per minute, and  $D$  = diameter of wheel in feet, whence  $D = \frac{6000}{\pi R} = \frac{1910}{R}$ .

MAXIMUM DIAMETER OF FLY-WHEEL ALLOWABLE FOR DIFFERENT NUMBERS OF REVOLUTIONS.

**Strains in the Rims of Fly-band Wheels Produced by Centrifugal Force.** (James B. Stanwood, Trans. A. S. M. E., xiv. 251.)  
—Mr. Stanwood mentions one case of a fly-band wheel where the periphery velocity on a 17' 9" wheel is over 7500 ft. per minute.

In band saw-mills the blade of the saw is operated successfully over wheels 8 and 9 ft. in diameter, at a periphery velocity of 9000 to 10,000 ft. per minute. These wheels are of cast iron throughout, of heavy thickness, with a large number of arms.

In shingle-machines and chipping-machines where cast-iron disks from 2 to 5 ft. in diameter are employed, with knives inserted radially, the speed is frequently 10,000 to 11,000 ft. per minute at the periphery.

If the rim of a fly-wheel alone be considered, the tensile strain in pounds per square inch of the rim section is  $T = \frac{V^2}{10}$  nearly, in which  $V =$  velocity in feet per second; but this strain is modified by the resistance of the arms, which prevent the uniform circumferential expansion of the rim, and induce a bending as well as a tensile strain. Mr. Stanwood discusses the strains in band-wheels due to transverse bending of a section of the rim between a pair of arms.

When the arms are few in number, and of large cross-section, the ring will be strained transversely to a greater degree than with a greater number of lighter arms. To illustrate the necessary rim thicknesses for various rim velocities, pulley diameters, number of arms, etc., the following table is given, based upon the formula

$$t = \frac{.475d}{N^2 \left( \frac{F}{V^2} - \frac{1}{10} \right)},$$

in which  $t =$  thickness of rim in inches,  $d =$  diameter of pulley in inches,  $N =$  number of arms,  $V =$  velocity of rim in feet per second, and  $F =$  the greatest strain in pounds per square inch to which any fibre is subjected. The value of  $F$  is taken at 6000 lbs. per sq. in.

**Thickness of Rims in Solid Wheels.**

Diameter of Pulley in inches.	Velocity of Rim in feet per second.	Velocity of Rim in feet per minute.	No. of Arms.	Thickness in inches.
24	50	3,000	6	2/10
24	88	5,280	6	15/32
48	88	5,280	6	15/16
108	184	11,040	16	2 1/2
108	184	11,040	36	1/2

If the limit of rim velocity for all wheels be assumed to be 88 ft. per second, equal to 1 mile per minute,  $F = 6000$  lbs., the formula becomes

$$t = \frac{.475d}{.67N^2} = 0.7 \frac{d}{N^2}.$$

When wheels are made in halves or in sections, the bending strain may be such as to make  $t$  greater than that given above. Thus, when the joint comes half way between the arms, the bending action is similar to a beam supported simply at the ends, uniformly loaded, and  $t$  is 50% greater. Then the formula becomes

$$t = \frac{.712d}{N^2 \left( \frac{F}{V^2} - \frac{1}{10} \right)}$$

or for a fixed maximum rim velocity of 88 ft. per second and  $F = 6000$  lbs.,

$t = \frac{1.05d}{N^2}$ . In segmental wheels it is preferable to have the joints opposite the arms. Wheels in halves, if very thin rims are to be employed, should have double arms along the line of separation,

Attention should be given to the proportions of large receiving and tightening pulleys. The thickness of rim for a 48-in. wheel (shown in table) with a rim velocity of 88 ft. per second, is 15/16 in. Many wrecks have been caused by the failure of receiving or tightening pulleys whose rims have been too thin. Fly-wheels calculated for a given coefficient of steadiness are frequently lighter than the minimum safe weight. This is true especially of large wheels. A rough guide to the minimum weight of wheels can be deduced from our formulæ. The arms, hub, lugs, etc., usually form from one quarter to one third the entire weight of the wheel. If  $b$  represents the of a wheel in inches, the weight of the rim (considered as a simple annular ring) will be  $w = .82dtb$  lbs. If the limit of speed is 88 ft. per second, then for solid wheels  $t = 0.7d \div N^2$ . For sectional wheels (joint between arms)  $t = 1.05d \div N^2$ . Weight of rim for solid wheels,  $w = .57d^2b \div N^2$  in pounds. Weight of rim in sectional wheels with joints between arms,  $w = .86d^2b \div N^2$  in pounds. Total weight of wheel: for solid wheel,  $W = .76d^2b \div N^2$  to  $.86d^2b \div N^2$ , in pounds. For segmental wheels with joint between arms,  $W = 1.05d^2b \div N^2$  to  $1.3d^2b \div N^2$ , in pounds.

(This subject is further discussed by Mr. Stanwood, in vol. xv., and by Prof. Gaetano Lanza, in vol. xvi., Trans. A. S. M. E.)

**A Wooden Rim Fly-wheel**, built in 1891 for a pair of Corliss engines at the Amoskeag Mfg. Co.'s mill, Manchester, N. H., is described by C. H. Manning in Trans. A. S. M. E., xiii, 618. It is 30 ft. diam. and 108 in. face. The rim is 12 inches thick, and is built up of 44 courses of ash plank, 2, 3, and 4 inches thick, reduced about 1/2 inch in dressing, set edgewise, so as to break joints, and glued and bolted together. There are two hubs and two sets of arms, 12 in each, all of cast iron. The weights are as follows:

Weight (calculated) of ash rim.....	31,855 lbs.
“ of 24 arms (foundry 45,020).....	40,349 “
“ “ 2 hubs ( “ 35,030) .....	31,394 “
Counter-weights in 6 arms.....	664 “
Total, excluding bolts and screws.....	104,262 ± “

The wheel was tested at 76 revs. per min., being a surface speed of nearly 7200 feet per minute.

Mr. Manning discusses the relative safety of cast iron and of wooden wheels as follows: As for safety, the speeds being the same in both cases, the hoop tension in the rim per unit of cross-section would be directly as the weight per cubic unit; and its capacity to stand the strain directly as the tensile strength per square unit; therefore the tensile strengths divided by the weights will give relative values of different materials. Cast iron weighing 450 lbs. per cubic foot and with a tensile strength of 1,440,000 lbs. per square foot would give a value of  $1,440,000 \div 450 = 3200$ , whilst ash, of which the rim was made, weighing 34 lbs. per cubic foot, and with 1,152,000 lbs. tensile strength per square foot, gives a result  $1,152,000 \div 34 = 33,882$ , and  $33,882 \div 3200 = 10.58$ , or the wood-rimmed pulley is ten times safer than the cast-iron when the castings are good. This would allow the wood-rimmed pulley to increase its speed to  $\sqrt{10.58} = 3.25$  times that of a sound cast-iron one with equal safety.

**Wooden Fly-wheel of the Willimantic Linen Co.** (Illustrated in *Power*, March, 1893.)—Rim 28 ft. diam., 110 in. face. The rim is carried upon three sets of arms, one under the centre of each belt, with 12 arms in each set.

The material of the rim is ordinary whitewood,  $\frac{7}{8}$  in. in thickness, cut into segments not exceeding 4 feet in length, and either 5 or 8 inches in width. These were assembled by building a complete circle 13 inches in width, first with the 8 inch inside and the 5-inch outside, and then beside it another circle with the widths reversed, so as to break joints. Each piece as it was added was brushed over with glue and nailed with three-inch wire nails to the pieces already in position. The nails pass through three and into the fourth thickness. At the end of each arm four 14-inch bolts secure the rim, the ends being covered by wooden plugs glued and driven into the face of the wheel.

**Wire-wound Fly-wheels for Extreme Speeds.** (*Eng'g News*, August 2, 1890.)—The power required to produce the Mannesmann tubes is very large, varying from 2000 to 10,000 H.P., according to the dimensions of the tube. Since this power is only needed for a short time (it takes only 30 to 45 seconds to convert a bar 10 to 12 ft. long and 4 in. in diameter into a tube), and then some time elapses before the next bar is ready, an engine of 1200 H.P. provided with a large fly-wheel for storing the energy will supply power enough for one set of rolls. These fly-wheels are so large and run at such great speeds that the ordinary method of constructing them cannot be followed. A wheel at the Mannesmann Works, made in Komotau, Hungary, in the usual manner, broke at a tangential velocity of 125 ft. per second. The fly-wheels designed to hold at more than double this speed consist of a cast-iron hub to which two steel disks, 20 ft. in diameter, are bolted; around the circumference of the wheel thus formed 70 tons of No. 5 wire are wound under a tension of 50 lbs. In the Mannesmann Works at Landore, Wales, such a wheel makes 240 revolutions a minute, corresponding to a tangential velocity of 15,080 ft. or 2.85 miles per minute.

## THE SLIDE-VALVE.

**Definitions.**—*Travel* = total distance moved by the valve.

*Throw of the Eccentric* = eccentricity of the eccentric = distance from the centre of the shaft to the centre of the eccentric disk =  $\frac{1}{2}$  the travel of the valve. (Some writers use the term "throw" to mean the whole travel of the valve.)

*Lap of the valve*, also called outside lap or steam-lap = distance the outer or steam edge of the valve extends beyond or laps over the steam edge of the port when the valve is in its central position.

*Inside lap*, or *exhaust-lap* = distance the inner or exhaust edge of the valve extends beyond or laps over the exhaust edge of the port when the valve is in its central position. The inside lap is sometimes made zero, or even negative, in which latter case the distance between the edge of the valve and the edge of the port is sometimes called exhaust clearance, or inside clearance.

*Lead of the valve* = the distance the steam-port is opened when the engine is on its centre and the piston is at the beginning of the stroke.

*Lead-angle* = the angle between the position of the crank when the valve begins to be opened and its position when the piston is at the beginning of the stroke.

The valve is said to have lead when the steam-port opens before the piston

begins its stroke. If the piston begins its stroke before the admission of steam begins the valve is said to have negative lead, and its amount is the lap of the edge of the valve over the edge of the port at the instant when the piston stroke begins.

*Lap-angle* = the angle through which the eccentric must be rotated to cause the steam edge to travel from its central position the distance of the lap.

*Angular advance* of the eccentric = lap-angle + lead angle.

*Linear advance* = lap + lead.

**Effect of Lap, Lead, etc., upon the Steam Distribution.**— Given valve-travel  $2\frac{3}{4}$  in., lap  $\frac{3}{4}$  in., lead  $\frac{1}{16}$  in., exhaust-lap  $\frac{1}{8}$  in., required crank position for admission, cut-off, release and compression, and greatest port-opening. (Halsey on Slide-valve Gears.) Draw a circle of diameter  $fh$  = travel of valve. From  $O$  the centre set off  $Oa$  = lap and  $ab$  = lead, erect perpendiculars  $Oe, ac, bd$ ; then  $ec$  is the lap-angle and  $cd$  the lead-angle, measured as arcs. Set off  $fg = cd$ , the lead-angle, then  $Og$  is the position of the crank for steam admission. Set off  $2ec + cd$  from  $h$  to  $i$ ; then  $Oi$  is the crank-angle for cut-off, and  $fk \div fh$  is the fraction of stroke completed at cut-off. Set off  $Ol =$  exhaust-lap and draw  $lm$ ;  $em$  is the exhaust-lap angle. Set off  $hn = ec + cd - em$ , and  $On$  is the position of crank at release. Set off  $fp = ec + cd + em$ , and  $Op$  is the position of crank for compression,  $fo \div fh$  is the fraction of stroke completed at release, and  $hq \div hf$  is the fraction of the return stroke completed when compression begins;  $Oh$ , the throw of the eccentric, minus  $Oa$  the lap, equals  $ah$  the maximum port-opening.

If a valve has neither lap nor lead, the line joining the centre of the eccen-

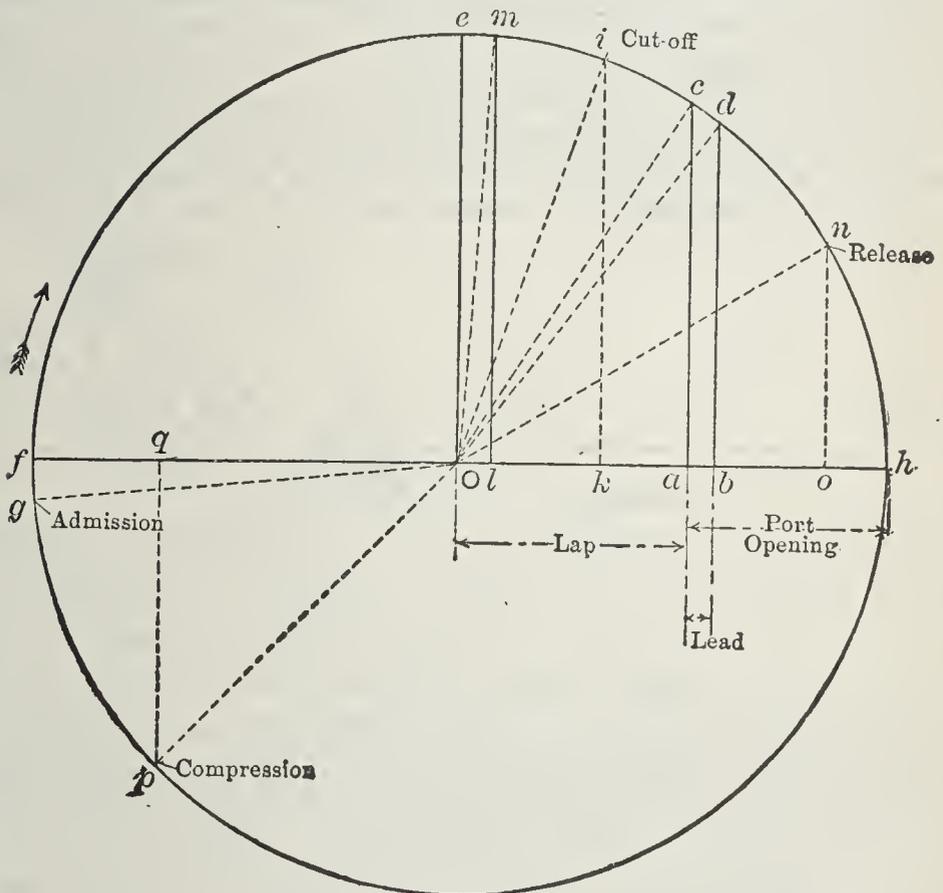

FIG. 146.

tric disk and the centre of the shaft being at right angles to the line of the crank, the engine would follow full stroke, admission of steam beginning at the beginning of the stroke and ending at the end of the stroke.

Adding lap to the valve enables us to cut off steam before the end of the stroke; the eccentric being advanced on the shaft an amount equal to the lap-angle enables steam to be admitted at the beginning of the stroke, as

before lap was added, and advancing it a further amount equal to the lead angle causes steam to be admitted before the beginning of the stroke.

Having given lap to the valve, and having advanced the eccentric on the shaft from its central position at right angles to the crank, through the angular advance = lap-angle and lead-angle, the four events, admission, cut-off, release or exhaust-opening, and compression or exhaust-closure, take place as follows: Admission, when the crank lacks the lead-angle of having reached the centre; cut-off, when the crank lacks two lap-angles and one lead-angle of having reached the centre. During the admission of steam the crank turns through a semicircle less twice the lap-angle. The greatest port-opening is equal to half the travel of the valve less the lap. Therefore for a given port-opening the travel of the valve must be increased if the lap is increased. When exhaust-lap is added to the valve it delays the opening of the exhaust and hastens its closing by an angle of rotation equal to the exhaust-lap angle, which is the angle through which the eccentric rotates from its middle position while the exhaust edge of the valve uncovers its lap. Release then takes place when the crank lacks one lap-angle and one lead-angle minus one exhaust-lap angle of having reached the centre, and compression when the crank lacks lap-angle + lead-angle + exhaust-lap angle of having reached the centre.

The above discussion of the relative position of the crank, piston, and valve for the different points of the stroke is accurate only with a connecting-rod of infinite length.

For actual connecting-rods the angular position of the rod causes a distortion of the position of the valve, causing the events to take place too late in the forward stroke and too early in the return. The correction of this distortion may be accomplished to some extent by setting the valve so as to give equal lead on both forward and return stroke, and by altering the exhaust-lap on one end so as to equalize the release and compression. F. A. Halsey, in his *Slide-valve Gears*, describes a method of equalizing the cut-off without at the same time affecting the equality of the lead. In designing slide-valves the effect of angularity of the connecting-rod should be studied on the drawing-board, and preferably by the use of a model.

**Sweet's Valve-diagram.**—To find outside and inside lap of valve for different cut-offs and compressions (see Fig. 147): Draw a circle whose

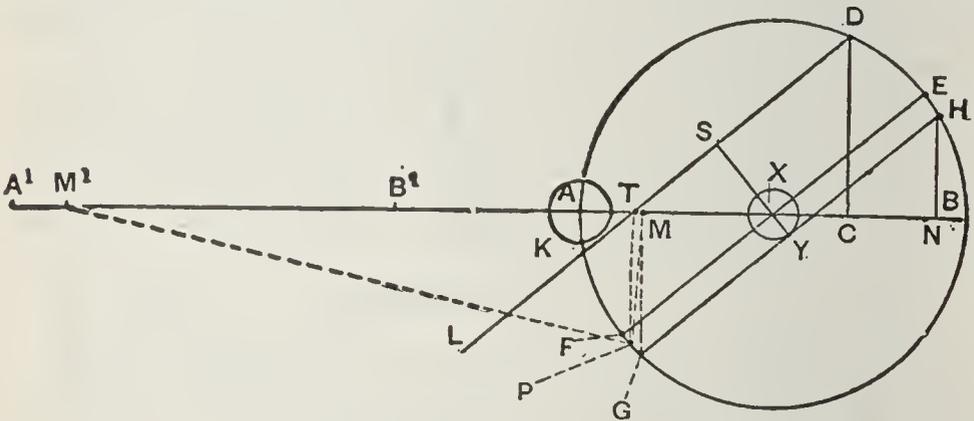

FIG. 147.—Sweet's Valve-diagram.

diameter equals travel of valve. Draw diameter  $BA$  and continue to  $A^1$ , so that the length  $AA^1$  bears the same ratio to  $XA$  as the length of connecting-rod does to length of engine-crank. Draw small circle  $K$  with a radius equal to lead. Lay off  $AC$  so that ratio of  $AC$  to  $AB$  = cut-off in parts of the stroke. Erect perpendicular  $CD$ . Draw  $DL$  tangent to  $K$ ; draw  $XS$  perpendicular to  $DL$ ;  $XS$  is then outside lap of valve.

To find release and compression: If there is no inside lap, draw  $FE$  through  $X$  parallel to  $DL$ .  $F$  and  $E$  will be position of crank for release and compression. If there is an inside lap, draw a circle about  $X$ , in which radius  $XY$  equals inside lap. Draw  $HG$  tangent to this circle and parallel to  $DL$ ; then  $H$  and  $G$  are crank position for release and compression. Draw  $HN$  and  $MG$ , then  $AN$  is piston position at release and  $AM$  piston position at compression,  $AB$  being considered stroke of engine.

To make compression alike on each stroke it is necessary to increase the inside lap on crank end of valve, and to decrease by the same amount the

lution still remains to be accomplished. When the crank-pin reaches the position  $A$ , that is to say, at the commencement of the stroke, the port is already opened by the space  $OC - OB = BC$ , called the lead. From this point forward till the crank occupies the position  $OE$  the port continues to open, but when the crank is at  $OE$  the valve has reached the furthest limit of its travel to the right, and then commences to return, till when in the position  $OF$  the edge of the valve just covers the steam-port, as is shown by the chord  $Oe'$ , being again common to both lap and valve circles. Hence when the crank occupies the position  $OF$  the cut-off takes place and the steam commences to expand, and continues to do so till the exhaust opens. For the return stroke the steam-port opens again at  $H'$  and closes at  $F'$ .

There remains the exhaust to be considered. When the line joining the centres of the eccentric and crank-shaft occupies the position opposite to  $OG$  at right angles to the line of dead centres, the crank is in the line  $OP$  at right angles to  $OE$ ; and as  $OP$  does not intersect either valve-circle the valve occupies its central position, and consequently closes the port by the amount of the inside lap. The crank must therefore move through such an angular distance that its line of direction  $OQ$  must intercept a chord on the valve-circle  $OK$  equal in length to the inside lap before the port can be opened to the exhaust. This point is ascertained precisely in the same manner as for the outside lap, namely, by drawing a circle from centre  $O$ , with a radius equal to the inside lap; this is the small inner circle in the figure. Where this circle intersects the two valve-circles we get four points which show the positions of the crank when the exhaust opens and closes during each revolution. Thus at  $Q$  the valve opens the exhaust on the side of the piston which we have been considering, while at  $R$  the exhaust closes and compression commences and continues till the fresh steam is readmitted at  $H$ .

Thus the diagram enables us to ascertain the exact position of the crank when each critical operation of the valve takes place. Making a *résumé* of these operations of one side of the piston, we have: Steam admitted before the commencement of the stroke at  $H$ . At the dead centre  $A$  the valve is already opened by the amount  $BC$ . At  $E$  the port is fully opened, and valve has reached one end of its travel. At  $F$  steam is cut off, consequently admission lasted from  $H$  to  $F$ . At  $P$  valve occupies central position, and ports are closed both to steam and exhaust. At  $Q$  exhaust opened, consequently expansion lasted from  $F$  to  $Q$ . At  $K$  exhaust opened to maximum extent, and valve reached the end of its travel to the left. At  $R$  exhaust closed, and compression begins and continues till the fresh steam is admitted at  $H$ .

**PROBLEM.**—The simplest problem which occurs is the following: Given the length of throw, the angle of advance of the eccentric, and the laps of the valve, find the angles of the crank at which the steam is admitted and cut off and the exhaust opened and closed. Draw the line  $OE$ , representing the half-travel of the valve or the throw of the eccentric at the given angle of advance with the perpendicular  $OG$ . Produce  $OE$  to  $K$ . On  $OE$  and  $OK$  as diameters describe the two valve-circles. With centre and radii equal to the given laps describe the outside and inside lap-circles. Then the intersection of these circles with the two valve-circles give points through which the lines  $OH$ ,  $OF$ ,  $OQ$ , and  $OR$  can be drawn. These lines give the required positions of the crank.

Numerous other problems will be found in Holmes on the Steam-engine, including problems in valve-setting and the application of the Zeuner diagram to link motion and to the Meyer valve-gear.

**Port Opening.**—The area of port opening should be such that the velocity of the steam in passing through it should not exceed 6000 ft. per min. The ratio of port area to piston area will then vary with the piston-speed as follows:

For speed of piston, } ft. per min.	100	200	300	400	500	600	700	800	900	1000	1200
Port area = piston } area ×	.017	.033	.05	.067	.083	.1	.107	.133	.15	.167	.2

For a velocity of 6000 ft. per min.,

$$\text{Port area} = \frac{\text{sq. of diam. of cyl.} \times \text{piston speed}}{7639}.$$

The length of the port opening may be equal to or something less than the diameter of the cylinder, and the width = area of port opening ÷ its length.

The bridge between steam and exhaust ports should be wide enough to prevent a leak of steam into the exhaust due to overtravel of the valve.

**Auchincloss** gives: Width of exhaust port = width of steam port +  $\frac{1}{2}$  travel of valve - width of bridge.

**Lead.** (From Peabody's Valve-gears.)—The lead, or the amount that the valve is open when the engine is on a dead point, varies, with the type and size of the engine, from a very small amount, or even nothing, up to  $\frac{3}{8}$  of an inch or more. Stationary-engines running at slow speed may have from  $\frac{1}{64}$  to  $\frac{1}{16}$  inch lead. The effect of compression is to fill the waste space at the end of the cylinder with steam; consequently, engines having much compression need less lead. Locomotive-engines having the valves controlled by the ordinary form of Stephenson link-motion may have a small lead when running slowly and with a long cut-off, but when at speed with a short cut-off the lead is at least  $\frac{1}{4}$  inch; and locomotives that have valve-gear which gives constant lead commonly have  $\frac{1}{4}$  inch lead. The lead angle is the angle the crank makes with the line of dead points at admission. It may vary from  $0^\circ$  to  $8^\circ$ .

**Inside Lead.**—Weisbach (vol. ii. p. 296) says: Experiment shows that the earlier opening of the exhaust ports is especially of advantage, and in the best engines the lead of the valve upon the side of the exhaust, or the inside lead; is  $\frac{1}{25}$  to  $\frac{1}{15}$ ; i.e., the slide-valve at the lowest or highest position of the piston has made an opening whose height is  $\frac{1}{25}$  to  $\frac{1}{15}$  of the whole throw of the slide-valve. The outside lead of the slide-valve or the lead on the steam side, on the other hand, is much smaller, and is often only  $\frac{1}{100}$  of the whole throw of the valve.

**Effect of Changing Outside Lap, Inside Lap, Travel and Angular Advance.** (Thurston.)

	Admission	Expansion	Exhaust	Compression
Incr. O.L.	is later, ceases sooner	occurs earlier, continues longer	is unchanged	begins at same point
Incr. I.L.	unchanged	begins as before, continues longer	occurs later, ceases earlier	begins sooner, continues longer
Incr. T.	begins sooner, continues longer	begins later, ceases sooner	begins later, ceases later	begins later, ends sooner
Incr. A.A.	begins earlier, period unaltered	begins sooner, per. the same	begins earlier, per. unchanged	begins earlier, per. the same

Zeuner gives the following relations (Weisbach-Dubois, vol. ii. p. 307):

If  $S$  = travel of valve,  $p$  = maximum port opening;

$L$  = steam-lap,  $l$  = exhaust-lap;

$$R = \text{ratio of steam-lap to half travel} = \frac{L}{.5S}, \quad L = \frac{R}{2} \times S;$$

$$r = \text{ratio of exhaust lap to half travel} = \frac{l}{.5S}, \quad l = \frac{r}{2} \times S;$$

$$S = 2p + 2L = 2p + R \times S; \quad S = \frac{2p}{1 - R}.$$

If  $\alpha$  = angle *HOF* between positions of crank at admission and at cut-off, and  $\beta$  = angle *QOR* between positions of crank at release and at compression, then  $R = \frac{1}{2} \frac{\sin(180^\circ - \alpha)}{\sin \frac{1}{2}\alpha}$ ;  $r = \frac{1}{2} \frac{\sin(180^\circ - \beta)}{\sin \frac{1}{2}\beta}$ .

**Ratio of Lap and of Port-opening to Valve-travel.**—The table on page 831, giving the ratio of lap to travel of valve and ratio of travel to port opening, is abridged from one given by Buel in Weisbach-Dubois, vol. ii. It is calculated from the above formulæ. Intermediate values may be found by the formulæ, or with sufficient accuracy by interpolation from the figures in the table. By the table on page 830 the crank-angle may be found, that is, the angle between its position when the engine is on the centre and its position at cut-off, release, or compression, when these are known in fractions of the stroke. To illustrate the use of the tables the following example is given by Buel: width of port = 2.2 in.; width of port opening = width of port + 0.3 in.; overtravel = 2.5 in.; length of connecting-rod =  $2\frac{1}{2}$  times stroke; cut-off = 0.75 of stroke; release = 0.95 of stroke; lead-angle,  $10^\circ$ . From the first table we find crank-angle =  $114.6$ .

**Relative Motions of Cross-head and Crank.**—If  $L$  = length of connecting-rod,  $R$  = length of crank,  $\theta$  = angle of crank with centre line of engine,  $D$  = displacement of cross-head from the beginning of its stroke,

$$D = R(1 - \cos \theta) + L - \sqrt{L^2 - R^2 \sin^2 \theta}.$$

**PERIODS OF ADMISSION, OR CUT-OFF, FOR VARIOUS LAPS AND TRAVELS OF SLIDE-VALVES.**

The two following tables are from Clark on the Steam-engine. In the first table are given the periods of admission corresponding to travels of valve of from 12 in. to 2 in., and laps of from 2 in. to 3/8 in., with 1/4 in. and 1/8 in. of lead. With greater leads than those tabulated, the steam would be cut off earlier than as shown in the table.

The influence of a lead of 5/16 in. for travels of from 15/8 in. to 6 in., and laps of from 1/2 in. to 1 1/2 in., as calculated for in the second table, is exhibited by comparison of the periods of admission in the table, for the same lap and travel. The greater lead shortens the period of admission, and increases the range for expansive working.

**Periods of Admission, or Points of Cut-off, for Given Travels and Laps of Slide-valves.**

**Diagram for Port-opening, Cut-off, and Lap.**—The diagram on the opposite page was published in *Power*, Aug., 1893. It shows at a glance the relations existing between the outside lap, steam port-opening, and cut-off in slide valve engines.

In order to use the diagram to find the lap, having given the cut-off and maximum port-opening, follow the ordinate representing the latter, taken on the horizontal scale, until it meets the oblique line representing the given cut-off. Then read off this height on the vertical lap scale. Thus, with a port-opening of 1¼ inch and a cut-off of .50, the intersection of the two lines occurs on the horizontal 3. The required lap is therefore 3 in.

If the cut-off and lap are given, follow the horizontal representing the latter until it meets the oblique line representing the cut-off. Then vertically below this read the corresponding port-opening on the horizontal scale.

If the lap and port-opening are given, the resulting cut-off may be ascertained by finding the point of intersection of the ordinate representing the port-opening with the horizontal representing the lap. The oblique line passing through the point of intersection will give the cut-off.

If it is desired to take lead into account, multiply the lead in inches by the numbers in the following table corresponding to the cut-off, and deduct the result from the lap as obtained from the diagram:

Cut-off.	Multiplier.	Cut-off.	Multiplier.
.20	4.717	.60	1.358
.25	3.731	.625	1.288
.30	3.048	.65	1.222
.33	2.717	.70	1.103
.375	2.381	.75	1.000
.40	2.171	.80	0.904
.45	1.930	.85	0.815
.50	1.706	.875	0.772
.55	1.515	.90	0.731

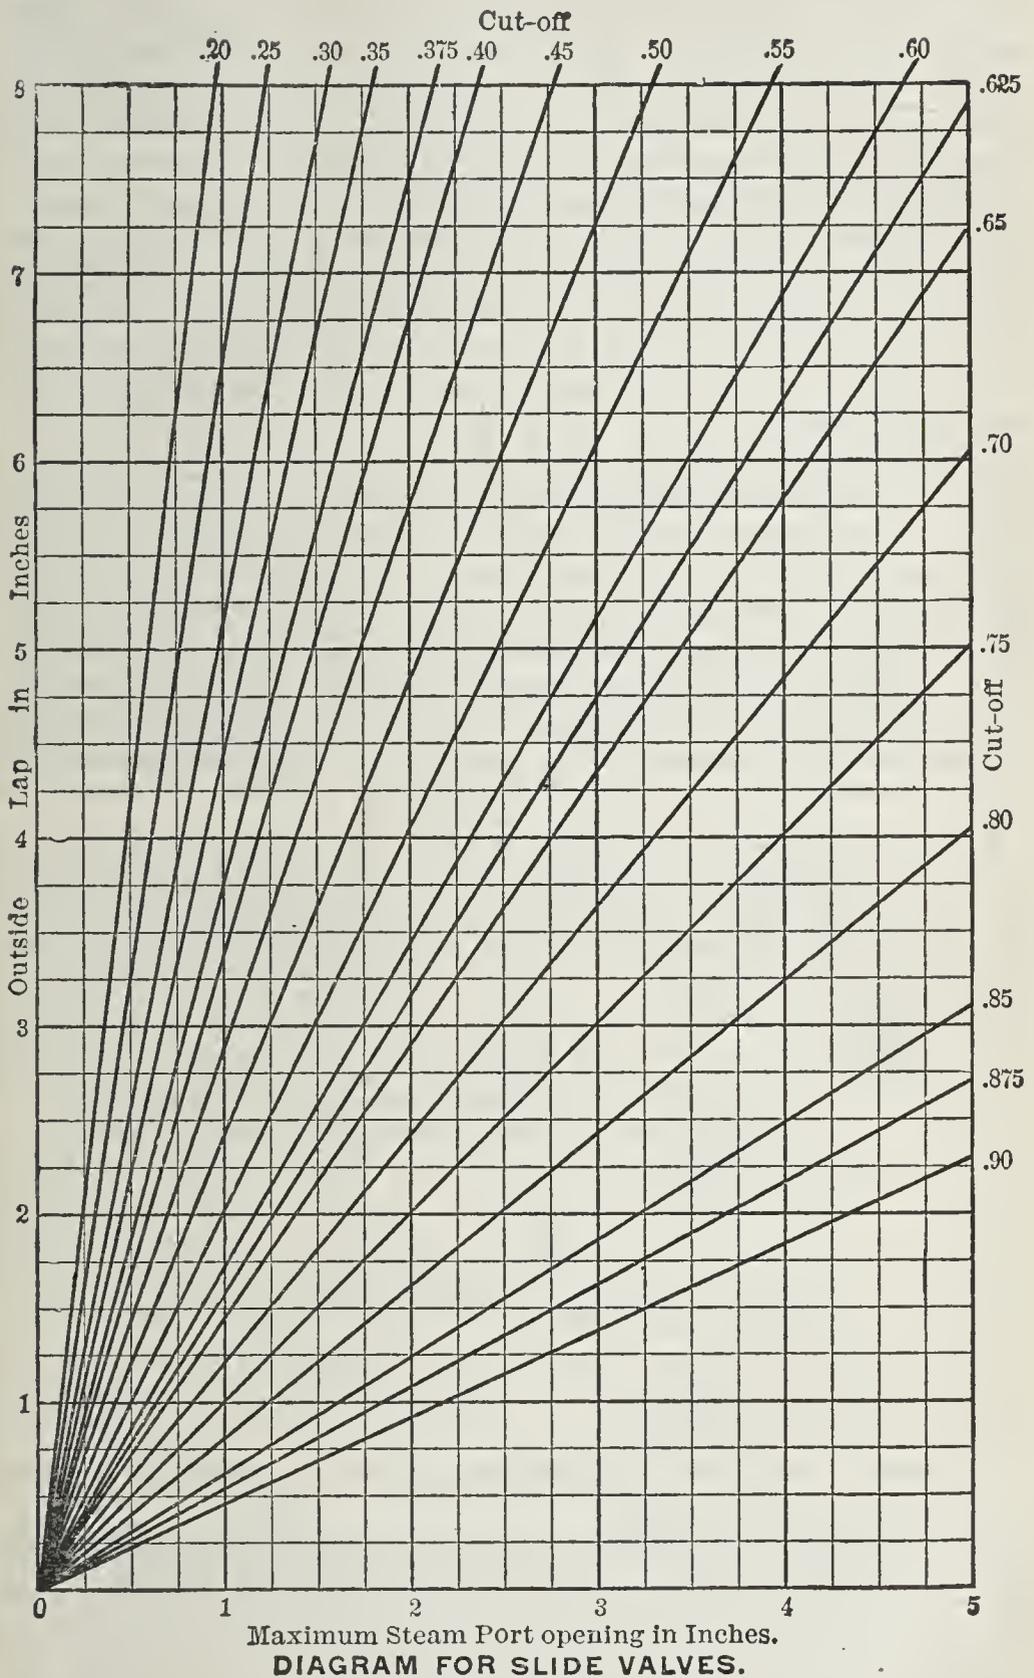

FIG. 149.

**Piston-valve.**—The piston-valve is a modified form of the slide-valve. The lap, lead, etc., are calculated in the same manner as for the common slide-valve. The diameter of valve and amount of port-opening are calculated on the basis that the most contracted portion of the steam-passage between the valve and the cylinder should have an area such that the velocity of steam through it will not exceed 6000 ft. per minute. The area of the opening around the circumference of the valve should be about double the area of the steam-passage, since that portion of the opening that is opposite from the steam-passage is of little effect.

**Setting the Valves of an Engine.**—The principles discussed above are applicable not only to the designing of valves, but also to adjustment of valves that have been improperly set; but the final adjustment of the eccentric and of the length of the rod depend upon the amount of lost motion, temperature, etc., and can be effected only after trial. After the valve has been set as accurately as possible when cold, the lead and lap for the forward and return strokes being equalized, indicator diagrams should be taken and the length of the eccentric-rod adjusted, if necessary, to correct slight irregularities.

**To Put an Engine on its Centre.**—Place the engine in a position where the piston will have nearly completed its outward stroke, and opposite some point on the cross-head, such as a corner, make a mark upon the guide. Against the rim of the pulley or crank-disk place a pointer and mark a line with it on the pulley. Then turn the engine over the centre until the cross-head is again in the same position on its inward stroke. This will bring the crank as much below the centre as it was above it before. With the pointer in the same position as before make a second mark on the pulley-rim. Divide the distance between the marks in two and mark the middle point. Turn the engine until the pointer is opposite this middle point, and it will then be on its centre. To avoid the error that may arise from the looseness of crank-pin and wrist-pin bearings, the engine should be turned a little above the centre and then be brought up to it, so that the crank-pin will press against the same brass that it does when the first two marks are made.

**Link-motion.**—Link-motions, of which the Stephenson link is the most commonly used, are designed for two purposes: first, for reversing the motion of the engine, and second, for varying the point of cut-off by varying the travel of the valve. The Stephenson link-motion is a combination of two eccentrics, called forward and back eccentrics, with a link connecting the extremities of the eccentric-rods; so that by varying the position of the link the valve-rod may be put in direct connection with either eccentric, or may be given a movement controlled in part by one and in part by the other eccentric. When the link is moved by the reversing lever into a position such that the block to which the valve-rod is attached is at either end of the link, the valve receives its maximum travel, and when the link is in mid-gear the travel is the least and cut-off takes place early in the stroke.

In the ordinary shifting-link with open rods, that is, not crossed, the lead of the valve increases as the link is moved from full to mid-gear, that is, as the period of steam admission is shortened. The variation of lead is equalized for the front and back strokes by curving the link to the radius of the eccentric-rods concavely to the axles. With crossed eccentric-rods the lead decreases as the link is moved from full to mid-gear. In a valve-motion with stationary link the lead is constant. (For illustration see Clark's Steam-engine, vol. ii. p. 22.)

The linear advance of each eccentric is equal to that of the valve in full gear, that is, to lap + lead of the valve, when the eccentric-rods are attached to the link in such position as to cause the half-travel of the valve to equal the eccentricity of the eccentric.

The angle between the two eccentric radii, that is, between lines drawn from the centre of the eccentric disks to the centre of the shaft equals  $180^\circ$  less twice the angular advance.

Buel, in Appleton's Cyclopaedia of Mechanics, vol. ii. p. 316, discusses the Stephenson link as follows: "The Stephenson link does not give a perfectly correct distribution of steam; the lead varies for different points of cut-off. The period of admission and the beginning of exhaust are not alike for both ends of the cylinder, and the forward motion varies from the backward.

"The correctness of the distribution of steam by Stephenson's link-motion depends upon conditions which, as much as the circumstances will permit, ought to be fulfilled, namely: 1. The link should be curved in the arc of a circle whose radius is equal to the length of the eccentric-rod. 2. The

eccentric-rods ought to be long; the longer they are in proportion to the eccentricity the more symmetrical will the travel of the valve be on both sides of the centre of motion. 3. The link ought to be short. Each of its points describes a curve in a vertical plane, whose ordinates grow larger the farther the considered point is from the centre of the link; and as the horizontal motion only is transmitted to the valve, vertical oscillation will cause irregularities. 4. The link-hanger ought to be long. The longer it is the nearer will be the arc in which the link swings to a straight line, and thus the less its vertical oscillation. If the link is suspended in its centre, the curves that are described by points equidistant on both sides from the centre are not alike, and hence results the variation between the forward and backward gear. If the link is suspended at its lower end, its lower half will have less vertical oscillation and the upper half more. 5. The centre from which the link-hanger swings changes its position as the link is lowered or raised, and also causes irregularities. To reduce them to the smallest amount the arm of the lifting-shaft should be made as long as the eccentric-rod, and the centre of the lifting-shaft should be placed at the height corresponding to the central position of the centre on which the link-hanger swings."

All these conditions can never be fulfilled in practice, and the variations in the lead and the period of admission can be somewhat regulated in an artificial way, but for one gear only. This is accomplished by giving different lead to the two eccentrics, which difference will be smaller the longer the eccentric-rods are and the shorter the link, and by suspending the link not exactly on its centre line but at a certain distance from it, giving what is called "the offset."

For application of the Zeuner diagram to link-motion, see Holmes on the Steam-engine, p. 290. See also Clark's Railway Machinery (1855), Clark's Steam-engine, Zeuner's and Anchinloss's Treatises on Slide-valve Gears, and Halsey's Locomotive Link Motion. (See page 859a.)

The following rules are given by the *American Machinist* for laying out a link for an upright slide-valve engine. By the term radius of link is meant the radius of the link-arc  $ab$ , Fig. 150, drawn through the centre of the slot;

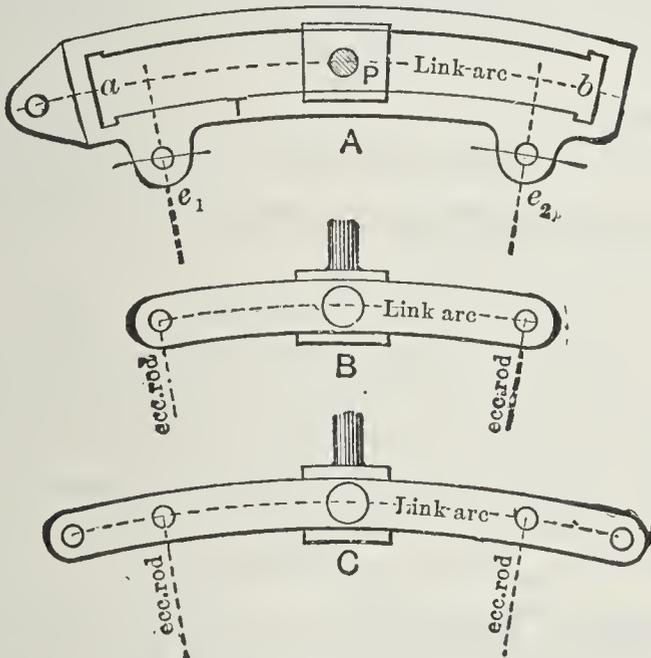

FIG. 150.

this radius is generally made equal to the distance from the centre of shaft to centre of the link-block pin  $P$  when the latter stands midway of its travel. The distance between the centres of the eccentric-rod pins  $e_1 e_2$  should not be less than  $2\frac{1}{2}$  times, and, when space will permit, three times the throw of the eccentric. By the throw we mean twice the eccentricity of the eccentric. The slot link is generally suspended from the end next to the forward eccentric at a point in the link-arc prolonged. This will give comparatively a small amount of slip to the link-block when the link is in forward gear; but this slip will be increased when the link is in backward gear. This increase

of slip is, however, considered of little importance, because marine engines, as a rule, work but very little in the backward gear. When it is necessary that the motion shall be as efficient in backward gear as in forward gear, then the link should be suspended from a point midway between the two eccentric-rod pins; in marine engine practice this point is generally located on the link-arc; for equal cut-offs it is better to move the point of suspension a small amount towards the eccentrics.

For obtaining the dimensions of the link in inches: Let  $L$  denote the length of the valve,  $B$  the breadth,  $p$  the absolute steam-pressure per sq. in., and  $R$  a factor of computation used as below; then  $R = .01 \sqrt{L \times B \times p}$ .

Breadth of the link.....	= $R \times 1.6$
Thickness $T$ of the bar.....	= $R \times .8$
Length of sliding-block.....	= $R \times 2.5$
Diameter of eccentric-rod pins.....	= $(R \times .7) + \frac{1}{4}$
Diameter of suspension-rod pin.....	= $(R \times .6) + \frac{1}{4}$
Diameter of suspension-rod pin when overhung..	= $(R \times .8) + \frac{1}{4}$
Diameter of block-pin when overhung.....	= $R + \frac{1}{4}$
Diameter of block-pin when secured at both ends	= $(R \times .8) + \frac{1}{4}$

The length of the link, that is, the distance from  $a$  to  $b$ , measured on a straight line joining the ends of the link-arc in the slot, should be such as to allow the centre of the link-block pin  $P$  to be placed in a line with the eccentric-rod pins, leaving sufficient room for the slip of the block. Another type of link frequently used in marine engines is the double-bar link, and this type is again divided into two classes: one class embraces those links which have the eccentric-rod ends as well as the valve-spindle end between the bars, as shown at  $B$  (with these links the travel of the valve is less than the throw of the eccentric); the other class embraces those links, shown at  $C$ , for which the eccentric-rods are made with fork-ends, so as to connect to studs on the outside of the bars, allowing the block to slide to the end of the link, so that the centres of the eccentric-rod ends and the block-pin are in line when in full gear, making the travel of the valve equal to the throw of the eccentric. The dimensions of these links when the distance between the eccentric-rod pins is  $2\frac{1}{2}$  to  $2\frac{3}{4}$  times the throw of eccentrics can be found as follows:

Depth of bars.....	= $(R \times 1.25) + \frac{1}{2}''$
Thickness of bars.....	= $(R \times .5) + \frac{1}{4}''$
Diameter of centre of sliding-block.....	= $R \times 1.3$

When the distance between the eccentric-rod pins is equal to 3 or 4 times the throw of the eccentrics, then

Depth of bars.....	= $(R \times 1.25) + \frac{3}{4}''$
Thickness of bars.....	= $(R \times .5) + \frac{1}{4}''$

All the other dimensions may be found by the first table. These are empirical rules, and the results may have to be slightly changed to suit given conditions. In marine engines the eccentric-rod ends for all classes of links have adjustable brasses. In locomotives the slot-link is usually employed, and in these the pin-holes have case-hardened bushes driven into the pin-holes, and have no adjustable brasses in the ends of the eccentric-rods. The link in  $B$  is generally suspended by one of the eccentric-rod pins; and the link in  $C$  is suspended by one of the pins in the end of the link, or by one of the eccentric-rod pins. (See note on Locomotive Link Motion in Appendix, p. 1077.)

**Other Forms of Valve-Gear,** as the Joy, Marshall, Hackworth, Bremme, Waischaert, Corliss, e c., are described in Clark's Steam-engine, vol. ii. The design of the Reynolds-Corliss valve-gear is discussed by A. H. Eldridge in *Power*, Sep. 1893. See also Henthorn on the Corliss engine. Rules for laying down the centre lines of the Joy valve-gear are given in *American Machinist*, Nov. 13, 1890. For Joy's "Fluid-pressure Reversing-valve," see *Eng'g*, May 25, 1894.

## GOVERNORS.

**Pendulum or Fly-ball Governor.**—The inclination of the arms of a revolving pendulum to a vertical axis is such that the height of the point of suspension  $h$  above the horizontal plane in which the centre of gravity of the balls revolve (assuming the weight of the rods to be small

compared with the weight of the ball(s) bears to the radius  $r$  of the circle described by the centres of the balls the ratio

$$\frac{h}{r} = \frac{\text{weight}}{\text{centrifugal force}} = \frac{w}{\frac{wv^2}{gr}} = \frac{gr}{v^2}$$

which ratio is independent of the weight of the balls,  $v$  being the velocity of the centres of the balls in feet per second.

If  $T$  = number of revolutions of the balls in 1 second,  $v = 2\pi rT = ar$ , in which  $a$  = the angular velocity, or  $2\pi T$ , and

$$h = \frac{gr^2}{v^2} = \frac{g}{4\pi^2 T^2}, \text{ or } h = \frac{0.8146}{T^2} \text{ feet} = \frac{9.775}{T^2} \text{ inches,}$$

$g$  being taken at 32.16. If  $N$  = number of revs. per minute,  $h = \frac{35190}{N^2}$  inches

For revolutions per minute.....	40	45	50	60	75
The height in inches will be.....	21.99	17.38	14.08	9.775	6.256

Number of turns per minute required to cause the arms to take a given angle with the vertical axis: Let  $l$  = length of the arm in inches from the centre of suspension to the centre of gyration, and  $\alpha$  the required angle; then

$$N = \sqrt{\frac{35190}{l \cos \alpha}} = 187.6 \sqrt{\frac{1}{l \cos \alpha}} = 187.6 \sqrt{\frac{1}{h}}$$

The simple governor is not isochronous; that is, it does not revolve at a uniform speed in all positions, the speed changing as the angle of the arms changes. To remedy this defect loaded governors, such as Porter's, are used. From the balls of a common governor whose collective weight is  $A$  let there be hung by a pair of links of lengths equal to the pendulum arms a load  $B$  capable of sliding on the spindle, having its centre of gravity in the axis of rotation. Then the centrifugal force is that due to  $A$  alone, and the effect of gravity is that due to  $A + 2B$ ; consequently the altitude for a given speed is increased in the ratio  $(A + 2B) : A$ , as compared with that of a simple revolving pendulum, and a given absolute variation in altitude produces a smaller proportionate variation in speed than in the common governor. (Rankine, S. E., p. 551.)

For the weighted governor let  $l$  = the length of the arm from the point of suspension to the centre of gravity of the ball, and let the length of the suspending-link,  $l_1$  = the length of the portion of the arm from the point of suspension of the arm to the point of attachment of the link;  $G$  = the weight of one ball,  $Q$  = half the weight of the sliding weight,  $h$  = the height of the governor from the point of suspension to the plane of revolution of the balls,  $a$  = the angular velocity =  $2\pi T$ ,  $T$  being the number of revolutions per

second; then  $a = \sqrt{\frac{32.16}{h} \left(1 + \frac{2l_1 Q}{l G}\right)}$ ;  $h = \frac{32.16}{a^2} \left(1 + \frac{2l_1 Q}{l G}\right)$  in feet, or

$h = \frac{35190}{N^2} \left(1 + \frac{2l_1 Q}{l G}\right)$  in inches,  $N$  being the number of revolutions per minute.

For various forms of governor see App. Cycl. Mech., vol. ii. 61, and Clark's Steam-engine, vol. ii. p. 65.

**To Change the Speed of an Engine Having a Fly-ball Governor.**—A slight difference in the speed of a governor changes the position of its weights from that required for full load to that required for no load. It is evident therefore that, whatever the speed of the engine, the normal speed of the governor must be that for which the governor was designed; i.e., the speed of the governor must be kept the same. To change the speed of the engine the problem is to so adjust the pulleys which drive the governor that the engine at its new speed shall drive it just as fast as it was driven at its original speed. In order to increase the engine-speed we must decrease the pulley upon the shaft of the engine, i.e., the driver, or increase that on the governor, i.e., the driven, in the proportion that the speed of the engine is to be increased.

**Fly-wheel or Shaft Governors.**—At the Centennial Exhibition in 1876 there were shown a few steam-engines in which the governors were contained in the fly-wheel or band-wheel, the fly-balls or weights revolving around the shaft in a vertical plane with the wheel and shifting the eccentric so as automatically to vary the travel of the valve and the point of cut-off. This form of governor has since come into extensive use, especially for high-speed engines. In its usual form two weights are carried on arms the ends of which are pivoted to two points on the pulley near its circumference, 180° apart. Links connect these arms to the eccentric. The eccentric is not rigidly keyed to the shaft but is free to move transversely across it for a certain distance, having an oblong hole which allows of this movement. Centrifugal force causes the weights to fly towards the circumference of the wheel and to pull the eccentric into a position of minimum eccentricity. This force is resisted by a spring attached to each arm which tends to pull the weights towards the shaft and shift the eccentric to the position of maximum eccentricity. The travel of the valve is thus varied, so that it tends to cut off earlier in the stroke as the engine increases its speed. Many modifications of this general form are in use. For discussions of this form of governor see Hartnell, Proc. Inst. M. E., 1882, p. 408; Trans. A. S. M. E., ix. 300; xi. 1081; xiv. 92; xv. 929; Modern Mechanism, p. 399; Whitham's Constructive Steam Engineering; J. Begtrup, *Am. Mach.*, Oct. 19 and Dec. 14, 1893, Jan. 18 and March 1, 1894.

**Calculation of Springs for Shaft-governors.** (Wilson Hartnell, Proc. Inst. M. E., Aug. 1882.)—The springs for shaft-governors may be conveniently calculated as follows, dimensions being in inches:

Let  $W$  = weight of the balls or weights, in pounds;

$r_1$  and  $r_2$  = the maximum and minimum radial distances of the centre of the balls or of the centre of gravity of the weights;

$l_1$  and  $l_2$  = the leverages, i.e., the perpendicular distances from the centre of the weight-pin to a line in the direction of the centrifugal force drawn through the centre of gravity of the weights or balls at radii  $r_1$  and  $r_2$ ;

$m_1$  and  $m_2$  = the corresponding leverages of the springs;

$C_1$  and  $C_2$  = the centrifugal forces, for 100 revolutions per minute, at radii  $r_1$  and  $r_2$ ;

$P_1$  and  $P_2$  = the corresponding pressures on the spring;

(It is convenient to calculate these and note them down for reference.)

$C_3$  and  $C_4$  = maximum and minimum centrifugal forces;

$S$  = mean speed (revolutions per minute);

$S_1$  and  $S_2$  = the maximum and minimum number of revolutions per minute;

$P_3$  and  $P_4$  = the pressures on the spring at the limiting number of revolutions ( $S_1$  and  $S_2$ );

$P_4 - P_3 = D$  = the difference of the maximum and minimum pressures on the springs;

$V$  = the percentage of variation from the mean speed, or the sensitiveness;

$t$  = the travel of the spring;

$u$  = the initial extension of the spring;

$v$  = the stiffness in pounds per inch;

$w$  = the maximum extension =  $u + t$ .

The mean speed and sensitiveness desired are supposed to be given. Then

$$S_1 = S - \frac{SV}{100};$$

$$S_2 = S + \frac{SV}{100};$$

$$C_1 = 0.28 \times r_1 \times W;$$

$$C_2 = 0.28 \times r_2 \times W;$$

$$P_1 = C_1 \times \frac{l_1}{m_1};$$

$$P_2 = C_2 \times \frac{l_2}{m_2};$$

$$P_3 = P_1 \times \left(\frac{S_1}{100}\right)^2;$$

$$P_4 = P_2 \times \left(\frac{S_2}{100}\right)^2;$$

$$v = \frac{D}{t}, \quad u = \frac{P_3}{v}, \quad w = \frac{P_4}{v}.$$

It is usual to give the spring-maker the values of  $P_4$  and of  $v$  or  $w$ . To ensure proper space being provided, the dimensions of the spring should be

calculated by the formulæ for strength and extension of springs, and the least length of the spring as compressed be determined.

$$\text{The governor-power} = \frac{P_3 + P_4}{2} \times \frac{t}{12}$$

With a straight centripetal line, the governor-power

$$= \frac{C_3 + C_4}{2} \times \left( \frac{r_2 - r_1}{12} \right).$$

For a preliminary determination of the governor-power it may be taken as equal to this in all cases, although it is evident that with a curved centripetal line it will be slightly less. The difference  $D$  must be constant for the same spring, however great or little its initial compression. Let the spring be screwed up until its minimum pressure is  $P_5$ . Then to find the speed  $P_6 = P_5 + D$ ,

$$S_5 = 100 \sqrt{\frac{P_5}{P_1}}; \quad S_6 = 100 \sqrt{\frac{P_6}{P_2}}$$

The speed at which the governor would be isochronous would be

$$100 \sqrt{\frac{D}{P_2 - P_1}}$$

Suppose the pressure on the spring with a speed of 100 revolutions, at the maximum and minimum radii, was 200 lbs. and 100 lbs., respectively, then the pressure of the spring to suit a variation from 95 to 105 revolutions will be  $100 \times \left(\frac{95}{100}\right)^2 = 90.2$  and  $200 \times \left(\frac{105}{100}\right)^2 = 220.5$ . That is, the increase of resistance from the minimum to the maximum radius must be  $220 - 90 = 130$  lbs.

The extreme speeds due to such a spring, screwed up to different pressures, are shown in the following table:

Revolutions per minute, balls shut.....	80	90	95	100	110	120
Pressure on springs, balls shut.....	64	81	90	100	121	144
Increase of pressure when balls open fully.....	130	130	130	130	130	130
Pressure on springs, balls open fully.....	194	211	220	230	251	274
Revolutions per minute, balls open fully. ....	98	102	105	107	112	117
Variation, per cent of mean speed ...	10	6	5	3	1	-1

The speed at which the governor would become isochronous is 114.

Any spring will give the right variation at some speed; hence in experimenting with a governor the correct spring may be found from any wrong one by a very simple calculation. Thus, if a governor with a spring whose stiffness is 50 lbs. per inch acts best when the engine runs at 95, 90 being its proper speed, then  $50 \times \left(\frac{90}{95}\right)^2 = 45$  lbs. is the stiffness of spring required.

To determine the speed at which the governor acts best, the springs may be screwed up until it begins to "hunt" and then slackened until the governor is as sensitive as is compatible with steadiness.

### CONDENSERS, AIR-PUMPS CIRCULATING-PUMPS, ETC.

**The Jet Condenser.** (Chiefly abridged from Seaton's Marine Engineering.)—The jet condenser is now uncommon in marine practice, being generally supplanted by the surface condenser. It is commonly used where fresh water is available for boiler feed. With the jet condenser a vacuum of 24 in. was considered fairly good, and 25 in. as much as was possible with most condensers; the temperature corresponding to 24 in. vacuum, or 3 lbs. pressure absolute, is 140°. In practice the temperature in the hot-well varies from 110° to 120°, and occasionally as much as 130° is maintained. To find the quantity of injection-water per pound of steam to be condensed: Let  $T_1$  = temperature of steam at the exhaust pressure;  $T_0$  = temperature of the cooling-

water;  $T_2$  = temperature of the water after condensation, or of the hot-well;  $Q$  = pounds of the cooling-water per lb. of steam condensed; then

$$Q = \frac{1114^\circ + 0.3T_1 - T_2}{T_2 - T_0}$$

Another formula is:  $Q = \frac{WH}{R}$ , in which  $W$  is the weight of steam condensed,  $H$  the units of heat given up by 1 lb. of steam in condensing, and  $R$  the rise in temperature of the cooling-water.

This is applicable both to jet and to surface condensers. The allowance made for the injection-water of engines working in the temperate zone is usually 27 to 30 times the weight of steam, and for the tropics 30 to 35 times; 30 times is sufficient for ships which are occasionally in the tropics, and this is what was usual to allow for general traders.

Area of injection orifice = weight of injection-water in lbs. per min.  $\div$  650 to 780.

A rough rule sometimes used is: Allow one fifteenth of a square inch for every cubic foot of water condensed per hour.

Another rule: Area of injection orifice = area of piston  $\div$  250.

The volume of the jet condenser is from one fourth to one half of that of the cylinder. It need not be more than one third, except for very quick-running engines.

**Ejector Condensers.**—For ejector or injector condensers (Bulkley's, Schutte's, etc.) the calculations for quantity of condensing-water is the same as for jet condensers.

**The Surface Condenser—Cooling Surface.**—Pecket found that with cooling water of an initial temperature of 68° to 77°, one sq. ft. of coil per plate condensed 21.5 lbs. of steam per hour, while Joule states that 100 lbs. per hour can be condensed. In practice, with the compound engine, brass condenser-tubes, 18 B.W.G. thick, 13 lbs. of steam per sq. ft. per hour, with the cooling-water at an initial temperature of 60°, is considered very fair work when the temperature of the feed-water is to be maintained at 120°. It has been found that the surface in the condenser may be half the heating surface of the boiler, and under some circumstances considerably less than this. In general practice the following holds good when the temperature of sea-water is about 60°:

Terminal pres., lbs., abs....	30	20	15	12½	10	8	6
Sq. ft. per I.H.P.....	3	2.50	2.25	2.00	1.80	1.60	1.50

For ships whose station is in the tropics the allowance should be increased by 20%, and for ships which occasionally visit the tropics 10% increase will give satisfactory results. If a ship is constantly employed in cold climates 10% less suffices

Whitham (Steam-engine Design, p. 283, also Trans. A. S. M. E., ix. 431) gives the following:  $S = \frac{WL}{ck(T_1 - t)}$ , in which  $S$  = condensing-surface in sq.

ft.;  $T_1$  = temperature Fahr. of steam of the pressure indicated by the vacuum-gauge;  $t$  = mean temperature of the circulating water, or the arithmetical mean of the initial and final temperatures;  $L$  = latent heat of saturated steam at temperature  $T_1$ ;  $k$  = perfect conductivity of 1 sq. ft. of the metal used for the condensing-surface for a range of 1° F. (or 557 B.T.U. per hour for brass, according to Isherwood's experiments);  $c$  = fraction denoting the efficiency of the condensing surface;  $W$  = pounds of steam condensed per hour. From experiments by Loring and Emery, on U.S.S. Dallas.

$c$  is found to be 0.323, and  $ck = 180$ ; making the equation  $S = \frac{WL}{180(T_1 - t)}$ .

Whitham recommends this formula for designing engines having independent circulating-pumps. When the pump is worked by the main engine the value of  $S$  should be increased about 10%.

Taking  $T_1$  at 135° F., and  $L = 1020$ , corresponding to 25 in. vacuum, and  $t$  for summer temperatures at 75°, we have:  $S = \frac{1020W}{180(135 - 75)} = \frac{17W}{180}$ .

For a mathematical discussion of the efficiency of surface condensers see a paper by T. E. Stanton in Proc. Inst. C. E., cxxxvi, June 1899, p. 321.

**Condenser Tubes** are generally made of solid-drawn brass tubes, and tested both by hydraulic pressure and steam. They are usually made of a composition of 68% of best selected copper and 32% of best Silesian spelter.

The Admiralty, however, always specify the tubes to be made of 70% of best selected copper and to have 1% of tin in the composition, and test the tubes to a pressure of 300 lbs. per sq. in. (Seaton.)

The diameter of the condenser tubes varies from  $\frac{1}{2}$  inch in small condensers, when they are very short, to 1 inch in very large condensers and long tubes. In the mercantile marine the tubes are, as a rule,  $\frac{3}{4}$  inch diameter externally, and 18 B.W.G. thick (0.049 inch); and 16 B.W.G. (0.065), under some exceptional circumstances. In the British Navy the tubes are also, as a rule,  $\frac{3}{4}$  inch diameter, and 18 to 19 B.W.G. thick, tinned on both sides; when the condenser is made of brass the Admiralty do not require the tubes to be tinned. Some of the smaller engines have tubes  $\frac{5}{8}$  inch diameter, and 19 B.W.G. thick. The smaller the tubes, the larger is the surface which can be got in a certain space.

In the merchant service the almost universal practice is to circulate the water through the tubes.

Whitham says the velocity of flow through the tubes should not be less than 400 nor more than 700 ft. per min.

**Tube-plates** are usually made of brass. Rolled-brass tube-plates should be from 1.1 to 1.5 times the diameter of tubes in thickness, depending on the method of packing. When the packings go completely through the plates the latter, but when only partly through the former, is sufficient. Hence, for  $\frac{3}{4}$ -inch tubes the plates are usually  $\frac{7}{8}$  to 1 inch thick with glands and tape-packings, and 1 to  $1\frac{1}{4}$  inch thick with wooden ferrules.

The tube-plates should be secured to their seatings by brass studs and nuts, or brass screw-bolts; in fact there must be no wrought iron of any kind inside a condenser. When the tube-plates are of large area it is advisable to stay them by brass-rods, to prevent them from collapsing.

**Spacing of Tubes, etc.**—The holes for ferrules, glands, or india-rubber are usually  $\frac{1}{4}$  inch larger in diameter than the tubes; but when absolutely necessary the wood ferrules may be only  $\frac{3}{32}$  inch thick.

The pitch of tubes when packed with wood ferrules is usually  $\frac{1}{4}$  inch more than the diameter of the ferrule-hole. For example, the tubes are generally arranged zigzag, and the number which may be fitted into a square foot of plate is as follows:

Pitch of Tubes.	No. in a sq. ft.	Pitch of Tubes.	No. in a sq. ft.	Pitch of Tubes.	No. in a sq. ft.
1"	172	1 $\frac{5}{32}$ "	128	1 $\frac{1}{4}$ "	110
1 $\frac{1}{16}$ "	150	1 $\frac{3}{16}$ "	121	1 $\frac{9}{32}$ "	106
1 $\frac{1}{8}$ "	137	1 $\frac{7}{32}$ "	116	1 $\frac{5}{16}$ "	99

**Quantity of Cooling Water.**—The quantity depends chiefly upon its initial temperature, which in Atlantic practice may vary from 40° in the winter of temperate zone to 80° in subtropical seas. To raise the temperature to 100° in the condenser will require three times as many thermal units in the former case as in the latter, and therefore only one third as much cooling-water will be required in the former case as in the latter.

$T_1$  = temperature of steam entering the condenser;  
 $T_0$  = " " circulating-water entering the condenser;  
 $T_2$  = " " " " leaving the condenser;  
 $T_3$  = " " water condensed from the steam;

$Q$  = pounds of circulating water per lb. of steam condensed  

$$= \frac{1114 + 0.3T_1 - T_3}{T_2 - T_0}$$

It is usual to provide pumping power sufficient to supply 40 times the weight of steam for general traders, and as much as 50 times for ships stationed in subtropical seas, when the engines are compound. If the circulating-pump is double-acting, its capacity may be  $\frac{1}{53}$  in the former and  $\frac{1}{42}$  in the latter case of the capacity of the low-pressure cylinder.

**Air-pump.**—The air-pump in all condensers abstracts the water condensed and the air originally contained in the water when it entered the boiler. In the case of jet-condensers it also pumps out the water of condensation and the air which it contained. The size of the pump is calculated from these conditions, making allowance for efficiency of the pump.

Ordinary sea-water contains, mechanically mixed with it, 1/20 of its volume of air when under the atmospheric pressure. Suppose the pressure in the condenser to be 2 lbs. and the atmospheric pressure 15 lbs., neglecting the effect of temperature, the air on entering the condenser will be expanded to 15/2 times its original volume; so that a cubic foot of sea-water, when it has entered the condenser, is represented by 19/20 of a cubic foot of water and 15/40 of a cubic foot of air.

Let  $q$  be the volume of water condensed per minute, and  $Q$  the volume of sea-water required to condense it; and let  $T_2$  be the temperature of the condenser, and  $T_1$  that of the sea-water.

Then  $19/20 (q + Q)$  will be the volume of water to be pumped from the condenser per minute,

$$\text{and } \frac{15}{40}(q + Q) \times \frac{T_2 + 461^\circ}{T_1 + 461^\circ} \text{ the quantity of air.}$$

If the temperature of the condenser be taken at 120°, and that of sea-water at 60°, the quantity of air will then be  $.418(q + Q)$ , so that the total volume to be abstracted will be

$$.95(q + Q) + .418(q + Q) = 1.368(q + Q).$$

If the average quantity of injection-water be taken at 26 times that condensed,  $q + Q$  will equal  $27q$ . Therefore, volume to be pumped from the condenser per minute =  $37q$ , nearly.

In surface condensation allowance must be made for the water occasionally admitted to the boilers to make up for waste, and the air contained in it, also for slight leak in the joints and glands, so that the air-pump is made about half as large as for jet-condensation.

The efficiency of a single-acting air-pump is generally taken at 0.5, and that of a double-acting pump at 0.35. When the temperature of the sea is 60°, and that of the (jet) condenser is 120°,  $Q$  being the volume of the cooling water and  $q$  the volume of the condensed water in cubic feet, and  $n$  the number of strokes per minute,

$$\text{The volume of the single-acting pump} = 2.74 \left( \frac{Q + q}{n} \right).$$

$$\text{The volume of the double-acting pump} = 4 \left( \frac{Q + q}{n} \right).$$

The following table gives the ratio of capacity of cylinder or cylinders to that of the air-pump; in the case of the compound engine, the low-pressure cylinder capacity only is taken.

Description of Pump.	Description of Engine.	Ratio.
Single-acting vertical.....	Jet-condensing, expansion $1\frac{1}{2}$ to 2....	6 to 8

**The Area through Valve-seats** and past the valves should not be less than will admit the full quantity of water for condensation at a velocity not exceeding 400 ft. per minute. In practice the area is generally in excess of this.

$$\text{Area through foot-valves} = D^2 \times S \div 1000 \text{ square inches.}$$

$$\text{Area through head-valves} = D^2 \times S \div 800 \text{ square inches.}$$

$$\text{Diameter of discharge-pipe} = D \times \sqrt{S} + 35 \text{ inches.}$$

$$D = \text{diam. of air-pump in inches, } S = \text{its speed in ft. per min.}$$

**James Tribe** (*Am. Mach.*, Oct. 8, 1891) gives the following rule for air-

pumps used with jet-condensers: Volume of single-acting air-pump driven by main engine = volume of low-pressure cylinder in cubic feet, multiplied by 3.5 and divided by the number of cubic feet contained in one pound of exhaust-steam of the given density. For a double-acting air-pump the same rule will apply, but the volume of steam for each stroke of the pump will be but one half. Should the pump be driven independently of the engine, then the relative speed must be considered. Volume of jet-condenser = volume of air-pump  $\times 4$ . Area of injection valve = vol. of air-pump in cubic inches  $\div 520$ .

**Circulating-pump.**—Let  $Q$  be the quantity of cooling water in cubic feet,  $n$  the number of strokes per minute, and  $S$  the length of stroke in feet.

$$\text{Capacity of circulating-pump} = Q \div n \text{ cubic feet.}$$

$$\text{Diameter " " " " } = 13.55 \sqrt{\frac{Q}{n \times S}} \text{ inches.}$$

The following table gives the ratio of capacity of steam-cylinder or cylinders to that of the circulating-pump:

Description of Pump.	Description of Engine.	Ratio.
Single-acting.	Expansive $1\frac{1}{2}$ to 2 times.	13 to 16
" "	" 3 to 5 "	20 to 25
" "	Compound.	25 to 30
Double "	Expansive $1\frac{1}{2}$ to 2 times.	25 to 30
" "	" 3 to 5 "	36 to 46
" "	Compound.	46 to 56

The clear area through the valve-seats and past the valves should be such that the mean velocity of flow does not exceed 450 feet per minute. The flow through the pipes should not exceed 500 ft. per min. in small pipes and 600 in large pipes.

For *Centrifugal Circulating-pumps*, the velocity of flow in the inlet and outlet pipes should not exceed 400 ft. per min. The diameter of the fan-wheel is from  $2\frac{1}{2}$  to 3 times the diam. of the pipe, and the speed at its periphery 450 to 500 ft. per min. If  $W$  = quantity of water per minute, in American gallons,  $d$  = diameter of pipes in inches,  $R$  = revolutions of wheel per min.,

$$d = \sqrt{\frac{W}{16.44}}; \text{ diam. of fan-wheel} = \text{not less than } \frac{1700}{R}. \text{ Breadth of blade at}$$

$$\text{tip} = \frac{W}{36d}. \text{ Diam. of cylinder for driving the fan} = \text{about } 2.8 \sqrt{\text{diam. of pipe,}} \\ \text{and its stroke} = 0.28 \times \text{diam. of fan.}$$

**Feed-pumps for Marine Engines.**—With surface-condensing engines the amount of water to be fed by the pump is the amount condensed from the main engine plus what may be needed to supply auxiliary engines and to supply leakage and waste. Since an accident may happen to the surface-condenser, requiring the use of jet-condensation, the pumps of engines fitted with surface-condensers must be sufficiently large to do duty under such circumstances. With jet-condensers and boilers using salt water the dense salt water in the boiler must be blown off at intervals to keep the density so low that deposits of salt will not be formed. Sea-water contains about  $1/32$  of its weight of solid matter in solution. The boiler of a surface-condensing engine may be worked with safety when the quantity of salt is four times that in sea-water. If  $Q$  = net quantity of feed-water required in a given time to make up for what is used as steam,  $n$  = number of times the saltiness of the water in the boiler is to that of sea-water, then the gross feed-

water =  $\frac{n}{n-1}Q$ . In order to be capable of filling the boiler rapidly each feed-pump is made of a capacity equal to twice the gross feed-water. Two feed-pumps should be supplied, so that one may be kept in reserve to be used while the other is out of repair. If  $Q$  be the quantity of net feed-water in cubic feet,  $l$  the length of stroke of feed-pump in feet, and  $n$  the number of strokes per minute,

$$\text{Diameter of each feed-pump plunger in inches} = \sqrt{\frac{550 \times Q}{n \times l}}.$$

If  $W$  be the net feed-water in pounds,

$$\text{Diameter of each feed-pump plunger in inches} = \sqrt{\frac{8.9 \times W}{n \times l}}$$

**An Evaporative Surface Condenser** built at the Virginia Agricultural College is described by James H. Fitts (Trans. A. S. M. E., xiv. 690). It consists of two rectangular end chambers connected by a series of horizontal rows of tubes, each row of tubes immersed in a pan of water. Through the spaces between the surface of the water in each pan and the bottom of the pan above air is drawn by means of an exhaust-fan. At the top of one of the end-chambers is an inlet for steam, and a horizontal diaphragm about midway causes the steam to traverse the upper half of the tubes and back through the lower. An outlet at the bottom leads to the air-pump. The condenser, exclusive of connection to the exhaust-fan, occupies a floor space of  $5' 4\frac{1}{2}'' \times 1' 9\frac{3}{4}''$ , and  $4' 1\frac{1}{2}''$  high. There are 27 rows of tubes, 8 in some and 7 in others; 210 tubes in all. The tubes are of brass, No. 20 B.W. G.,  $\frac{3}{4}''$  external diameter and  $4' 9\frac{1}{2}''$  in length. The cooling surface (internal) is 176.5 sq. ft. There are 27 cooling pans, each  $4' 9\frac{1}{2}'' \times 1' 9\frac{3}{4}''$ , and  $1 \frac{7}{16}''$  deep. These pans have galvanized iron bottoms which slide into horizontal grooves  $\frac{1}{4}''$  wide and  $\frac{1}{4}''$  deep, planed into the tube-sheets. The total evaporating surface is 234.8 sq. ft. Water is fed to every third pan through small cocks, and overflow-pipes feed the rest. A wood casing connects one side with a 30'' Buffalo Forge Co.'s disk-wheel. This wheel is belted to a  $3'' \times 4''$  vertical engine. The air-pump is  $5\frac{3}{4}''$  diameter with a 6'' stroke, is vertical and single-acting.

The action of this condenser is as follows: The passage of air over the water surfaces removes the vapor as it rises and thus hastens evaporation. The heat necessary to produce evaporation is obtained from the steam in the tubes, causing the steam to condense. It was designed to condense 800 lbs. steam per hour and give a vacuum of 22 in., with a terminal pressure in the cylinder of 20 lbs. absolute.

Results of tests show that the cooling-water required is practically equal in amount to the steam used by the engine. And since consumption of steam is reduced by the application of a condenser, its use will actually reduce the total quantity of water required. From a curve showing the rate of evaporation per square foot of surface in still air, and also one showing the rate when a current of air of about 2300 ft. per min. velocity is passed over its surface, the following approximate figures are taken:

Temp. F.	Evaporation, lbs. per sq. ft. per hour.		Temp. F.	Evaporation, lbs. per sq. ft. per hour.	
	Still Air.	Current.		Still Air.	Current.
100°	0.2	1.1	140°	0.8	5.0
110	0.25	1.6	150	1.1	6.7
120	0.4	2.5	160	1.5	9.5
130	0.6	3.5	170	2.0	...

**The Continuous Use of Condensing-water** is described in a series of articles in *Power*, Aug.-Dec., 1892. It finds its application in situations where water for condensing purposes is expensive or difficult to obtain.

In San Francisco J. H. Stut cools the water after it has left the hot-well by means of a system of pans upon the roof. These pans are shallow troughs of galvanized iron arranged in tiers, on a slight incline, so that the water flows back and forth for 1500 or 2000 ft., cooling by evaporation and radiation as it flows. The pans are about 5 ft. in width, and the water as it flows has a depth of about half an inch, the temperature being reduced from about 140° to 90°. The water from the hot-well is pumped up to the highest point of the cooling system and allowed to flow as above described, discharging finally into the main tank or reservoir, whence it again flows to the condenser as required. As the water in the reservoir lowers from evaporation, an auxiliary feed from the city mains to the condenser is operated, thereby keeping the amount of water in circulation practically constant. An accumulation of oil from the engines, with dust from the surrounding streets, makes a cleaning necessary about once in six weeks or two months. It is found by comparative trials, running condensing and non-condensing, that

about 50% less water is taken from the city mains when the whole apparatus is in use than when the engine is run non-condensing. 22 to 23 in. of vacuum are maintained. A better vacuum is obtained on a warm day with a brisk breeze blowing than on a cold day with but a slight movement of the air.

In another plant the water from the hot-well is sprayed from a number of fountains, and also from a pipe extending around its border, into a large pond, the exposure cooling it sufficiently for the obtaining of a good vacuum by its continuous use.

In the system patented by Messrs. See, of Lille, France, the water is discharged from a pipe laid in the form of a rectangle and elevated above a pond through a series of special nozzles, by which it is projected into a fine spray. On coming into contact with the air in this state of extreme division the water is cooled 40° to 50°, with a loss by evaporation of only one tenth of its mass, and produces an excellent vacuum. A 3000-H.P. cooler upon this system has been erected at Lannoy, one of 2500 H.P. at Madrid, and one of 1200 H.P. at Liege, as well as others at Roubaix and Tourcoing. The system could be used upon a roof if ground space were limited.

In the "self-cooling" system of H. R. Worthington the injection-water is taken from a tank, and after having passed through the condenser is discharged in a heated condition to the top of a cooling tower, where it is scattered by means of distributing-pipes and trickles down through a cellular structure made of 6-in. terra-cotta pipes, 2 ft. long, stood on end. The water is cooled by a blast of air furnished by a disk fan at the bottom of the tower and the absorption of heat caused by a portion of the water being vaporized, and is led to the tank to be again started on its circuit. (*Eng'g News*, March 5, 1896.)

In the evaporative condenser of T. Ledward & Co. of Brockley, London, the water trickles over the pipes of the large condenser or radiator, and by evaporation carries away the heat necessary to be abstracted to condense the steam inside. The condensing pipes are fitted with corrugations mounted with circular ribs, whereby the radiating or cooling surface is largely increased. The pipes, which are cast in sections about 76 in. long by 3½ in. bore, have a cooling surface of 26 sq. ft., which is found sufficient under favorable conditions to permit of the condensation of 20 to 30 lbs. of steam per hour when producing a vacuum of 13 lbs. per sq. in. In a condenser of this type at Rixdorf, near Berlin, a vacuum ranging from 24 to 26 in. of mercury was constantly maintained during the hottest weather of August. The initial temperature of the cooling-water used in the apparatus under notice ranged from 80° to 85° F., and the temperature in the sun, to which the condenser was exposed, varied each day from 100° to 115° F. During the experiments it was found that it was possible to run one engine under a load of 100 horse-power and maintain the full vacuum without the use of any cooling-water at all on the pipes, radiation afforded by the pipes alone sufficing to condense the steam for this power.

In Klein's condensing water-cooler, the hot water coming from the condenser enters at the top of a wooden structure about twenty feet in height, and is conveyed into a series of parallel narrow metal tanks. The water overflowing from these tanks is spread as a thin film over a series of wooden partitions suspended vertically about 3½ inches apart within the tower. The upper set of partitions, corresponding to the number of metal tanks, reaches half-way down the tower. From there down to the well is suspended a second set of partitions placed at right angles to the first set. This impedes the rapidity of the downflow of the water, and also thoroughly mixes the water, thus affording a better cooling. A fan-blower at the base of the tower drives a strong current of air with a velocity of about twenty feet per second against the thin film of water running down over the partitions. It is estimated that for an effectual cooling two thousand times more air than water must be forced through the apparatus. With such a velocity the air absorbs about two per cent of aqueous vapor. The action of the strong air-current is twofold: first, it absorbs heat from the hot water by being itself warmed by radiation; and, secondly, it increases the evaporation, which process absorbs a great amount of heat. These two cooling effects are different during the different seasons of the year. During the winter months the direct cooling effect of the cold air is greater, while during summer the heat absorption by evaporation is the more important factor. Taking all the year round, the effect remains very much the same. The evaporation is never so great that the deficiency of water would not be supplied by the additional amount of water resulting from the condensed steam, while in very cold winter months it may be necessary to occasionally rid the cistern of surplus water. It was found that the vacuum obtained by

this continual use of the same condensing-water varied during the year between 27.5 and 28.7 inches. The great saving of space is evident from the fact that only the five-hundredth part of the floor-space is required as if cooling tanks or ponds were used. For a 100-horse-power engine the floor-space required is about four square yards by a height of twenty feet. For one horse-power 3.6 square yards cooling-surface is necessary. The vertical suspension of the partitions is very essential. With a ventilator 50 inches in diameter and a tower 6 by 7 feet and 20 feet high, 10,500 gallons of water per hour were cooled from 104° F. to 68° F. The following record was made at Mannheim, Germany: Vacuum in condenser, 28.1 inches; temperature of condensing-water entering at top of tower, 104° to 108° F.; temperature of water leaving the cooler, 66.2° to 71.6° F. The engine was of the Sulzer compound type, of 120 horse-power. The amount of power necessary for the arrangement amounts to about three per cent of the total horse-power of the engine for the ventilator, and from one and one half to three per cent for the lifting of the water to the top of the cooler, the total being four and one half to six per cent.

A novel form of condenser has been used with considerable success in Germany and other parts of the Continent. The exhaust-steam from the engine passes through a series of brass pipes immersed in water, to which it gives up its heat. Between each section of tubes a number of galvanized disks are caused to rotate. These disks are cooled by a current of air supplied by a fan and pass down into the water, cooling it by abstracting the heat given out by the exhaust-steam and carrying it up where it is driven off by the air-current. The disks serve also to agitate the water and thus aid it in abstracting the heat from the steam. With 85 per cent vacuum the temperature of the cooling water was about 130° F., and a consumption of water for condensing is guaranteed to be less than a pound for each pound of steam condensed. For an engine 40 in. × 50 in., 70 revolutions per minute, 90 lbs. pressure, there is about 1150 sq. ft. of condensing-surface. Another condenser, 1600 sq. ft. of condensing-surface, is used for three engines, 32 in. × 48 in., 27 in. × 40 in., and 30 in. × 40 in., respectively.

—*The Steamship.*

**The Increase of Power** that may be obtained by adding a condenser giving a vacuum of 26 inches of mercury to a non-condensing engine may be approximated by considering it to be equivalent to a net gain of 12 pounds mean effective pressure per square inch of piston area. If  $A$  = area of piston in square inches,  $S$  = piston-speed in ft. per minute, then  $\frac{12AS}{33,000} = \frac{AS}{2750} = \text{H.P.}$  made available by the vacuum. If the vacuum = 13.2 lbs. per sq. in. = 27.9 in. of mercury, then  $\text{H.P.} = AS \div 2500$ .

*The saving of steam* for a given horse-power will be represented approximately by the shortening of the cut-off when the engine is run with the condenser. Clearance should be included in the calculation. To the mean effective pressure non-condensing, with a given actual cut-off, clearance considered, add 3 lbs. to obtain the approximate mean *total* pressure, condensing. From tables of expansion of steam find what actual cut-off will give this mean total pressure. The difference between this and the original actual cut-off, divided by the latter and by 100, will give the percentage of saving.

The following diagram (from catalogue of H. R. Worthington) shows the percentage of power that may be gained by attaching a condenser to a non-condensing engine, assuming that the vacuum is 12 lbs. per sq. in. The diagram also shows the mean pressure in the cylinder for a given initial pressure and cut-off, clearance and compression not considered.

The pressures given in the diagram are absolute pressures above a vacuum.

To find the mean effective pressure produced in an engine-cylinder with 90 lbs. gauge (= 105 lbs. absolute) pressure, cut-off at  $\frac{1}{4}$  stroke: find 105 in the left-hand or initial-pressure column, follow the horizontal line to the right until it intersects the oblique line that corresponds to the  $\frac{1}{4}$  cut-off, and read the mean total pressure from the row of figures directly above the point of intersection, which in this case is 63 lbs. From this subtract the mean absolute back pressure (say 3 lbs. for a condensing engine and 15 lbs. for a non-condensing engine exhausting into the atmosphere) to obtain the mean effective pressure, which in this case, for a non-condensing engine, gives 48 lbs. To find the gain of power by the use of a condenser with this engine, read on the lower scale the figures that correspond in position to 48 lbs. in the upper row, in this case 25%. As the diagram does not take into consideration clearance or compression, the results are only approximate.

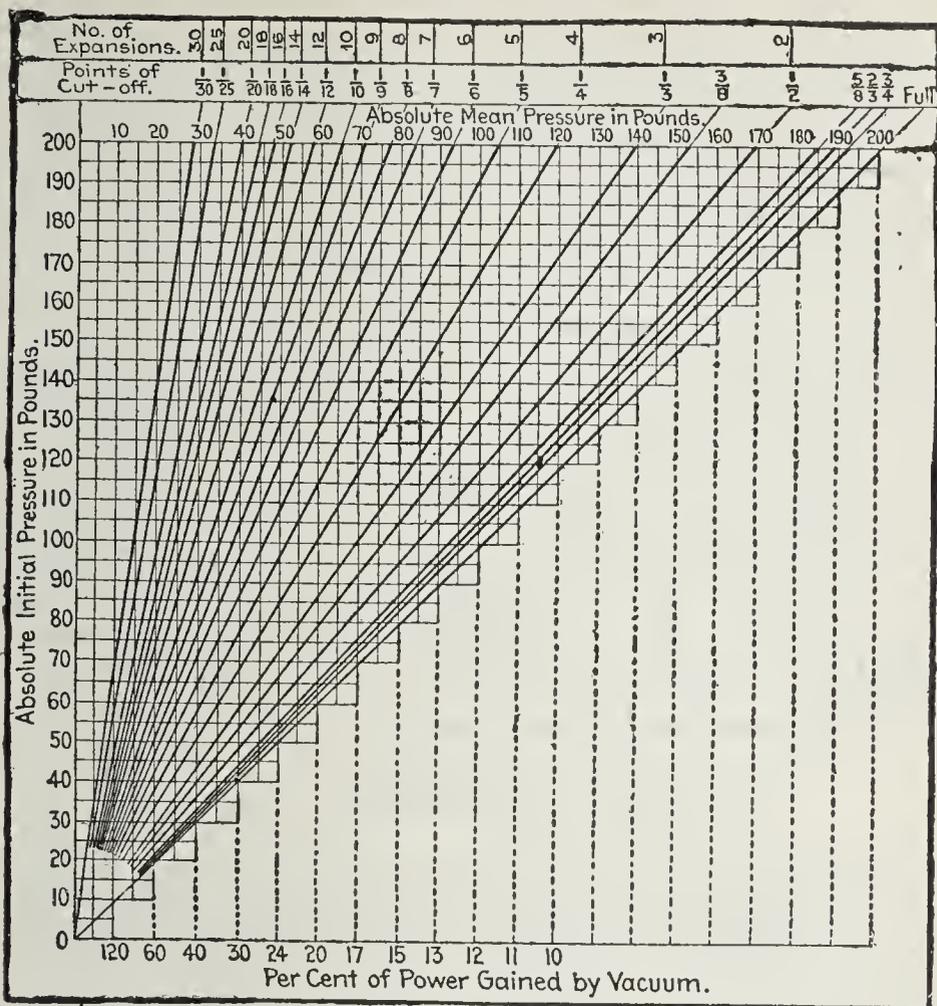

FIG. 151.

**Evaporators and Distillers** are used with marine engines for the purpose of providing fresh water for the boilers or for drinking purposes.

*Weir's Evaporator* consists of a small horizontal boiler, contrived so as to be easily taken to pieces and cleaned. The water in it is evaporated by the steam from the main boilers passing through a set of tubes placed in its bottom. The steam generated in this boiler is admitted to the low-pressure valve-box, so that there is no loss of energy, and the water condensed in it is returned to the main boilers.

In *Weir's Feed-heater* the feed-water before entering the boiler is heated up very nearly to boiling-point by means of the waste water and steam from the low-pressure valve-box of a compound engine.

## GAS, PETROLEUM, AND HOT-AIR ENGINES.

**Gas-engines.**—For theory of the gas-engine, see paper by Dugald Clerk, Proc. Inst. C. E. 1882, vol. lxi.; and Van Nostrand's Science Series, No. 62. See also Wood's Thermodynamics. Three standard works on gas-engines are "A Practical Treatise on the 'Otto' Cycle Gas-engine," by Wm. Norris; "A Text-book on Gas, Air, and Oil Engines," by Bryan Donkin; and "The Gas and Oil Engine," by Dugald Clerk (6th edition, 1896).

In the ordinary type of single-cylinder gas-engine (for example the Otto) known as a four-cycle engine one ignition of gas takes place in one end of the cylinder every two revolutions of the fly-wheel, or every two double strokes. The following sequence of operations takes place during four consecutive strokes: (a) inspiration during an entire stroke; (b) compression during the second (return) stroke; (c) ignition at the dead-point, and expansion during the third stroke; (d) expulsion of the burnt gas during the fourth (return) stroke. Beau de Rochas in 1862 laid down the law that there are

four conditions necessary to realize the best results from the elastic force of gas: (1) The cylinders should have the greatest capacity with the smallest circumferential surface; (2) the speed should be as high as possible; (3) the cut-off should be as early as possible; (4) the initial pressure should be as high as possible. In modern engines it is customary for ignition to take place, not at the dead point, as proposed by Beau de Rochas, but somewhat later, when the piston has already made part of its forward stroke. At first sight it might be supposed that this would entail a loss of power, but experience shows that though the area of the diagram is diminished, the power registered by the friction-brake is greater. Starting is also made easier by this method of working. (The Simplex Engine, Proc. Inst. M. E. 1889.)

In the Otto engine the mixture of gas and air is compressed to about 3 atmospheres. When explosion takes place the temperature suddenly rises to somewhere about 2900° F. (Robinson.)

The two great sources of waste in gas-engines are: 1. The high temperature of the rejected products of combustion; 2. Loss of heat through the cylinder walls to the water-jacket. As the temperature of the water-jacket is increased the efficiency of the engine becomes higher.

With ordinary coal-gas the consumption may be taken at 20 cu. ft. per hour per I.H.P., or 24 cu. ft. per brake H.P. The consumption will vary with the quality of the gas. When burning Dowson producer-gas the consumption of anthracite (Welsh) coal is about 1.3 lbs. per I.H.P. per hour for ordinary working. With large twin engines, 100 H.P., the consumption is reduced to about 1.1 lb. The mechanical efficiency or B.H.P. ÷ I.H.P. in ordinary engines is about 85%; the friction loss is less in larger engines.

**Efficiency of the Gas-engine.** (Thurston on Heat as a Form of Energy.)

Heat transferred into useful work.....	17%
“ “ to the jacket-water.....	52
“ lost in the exhaust-gas.....	16
“ “ by conduction and radiation.....	15
	— 83%

This represents fairly the distribution of heat in the best forms of gas-engine. The consumption of gas in the best engines ranges from a minimum of 18 to 20 cu. ft. per I.H.P. per hour to a maximum exceeding in the smaller engines 25 cu. ft. or 30 cu. ft. In small engines the consumption per brake horse-power is one third greater than these figures.

The report of a test of a 170-H.P. Crossley (Otto) gas-engine in England, 1892, using producer-gas, shows a consumption of but .85 lb. of coal per H.P. hour, or an absolute combined efficiency of 21.3% for the engine and producer. The efficiency of the engine alone is in the neighborhood of 25%.

The Taylor gas-producer is used in connection with the Otto gas-engine at the Otto Gas-engine Works in Philadelphia. The only loss is due to radiation through the walls of the producer and a small amount of heat carried off in the water from the scrubber. Experiments on a 100-H.P. engine show a consumption of 97/100 lb. of carbon per I.H.P. per hour. This result is superior to any ever obtained on a steam-engine. (*Iron Age*, 1893.)

**Tests of the Simplex Gas-engine.** (Proc. Inst. M. E. 1889.)—Cylinder  $7\frac{7}{8} \times 15\frac{3}{4}$  in., speed 160 revs. per min. Trials were made with town gas of a heating value of 607 heat-units per cubic foot, and with Dowson gas, rich in CO, of about 150 heat-units per cubic foot.

	Town Gas.			Dowson Gas.		
	1.	2.	3.	1.	2.	3.
Effective H.P.....	6.70	8.67	9.28	7.12	3.61	5.26
Gas per H.P. per hour, cu. ft..	21.55	20.12	20.73	88.03	114.85	97.88
Water per H.P. per hour, lbs.	54.7	44.4	43.8	58.3		
Temp. water entering, F.....	51°	51°	51°	48°		
“ “ effluent.....	135°	144°	172°	144°		

The gas volume is reduced to 32° F. and 30 in barometer. A 50-H.P. engine working 35 to 40 effective H.P. with Dowson generator consumed 51 lbs. English anthracite per hour, equal to 1.48 to 1.3 lbs. per effective H.P. A 16-H.P. engine working 12 H.P. used 19.4 cu. ft. of gas per effective H.P.

**A 320-H.P. Gas-engine.**—The flour-mills of M. Leblanc, at Pantin, France, have been provided with a 320-horse-power fuel-gas engine of the Simplex type. With coal-gas the machine gives 450 horse-power. There is one cylinder, 34.8 in. diam.; the piston-stroke is 40 in.; and the speed 100 revs.

per min. Special arrangements have been devised in order to keep the different parts of the machine at appropriate temperatures. The coal used is 0.812 lb. per indicated or 1.03 lb. per brake horse-power. The water used is 8¾ gallons per brake horse-power per hour.

**Test of an Otto Gas-engine.** (*Jour. F. I.*, Feb. 1890, p. 115.)—Engine 7 H.P. nominal; working capacity of cylinder .2594 cu. ft.; clearance space .1796 cu. ft.

**Test of the Clerk Gas-engine.** (*Proc. Inst. C. E.* 1882, vol. lxix.)—Cylinder 6 × 12 in., 150 revs. per min.; mean available pressure, 70.1 lbs., 9 I.H.P.; maximum pressure, 220 lbs. per sq. in. above atmosphere; pressure before ignition, 41 lbs. above atm.; temperature before compression, 60° F., after compression, 313° F.; temperature after ignition calculated from pressure, 2800° F.; gas required per I.H.P. per hour, 22 cu. ft.

More Recent Tests of gas-engines, 1898, have given higher economical results than those above quoted. The gas-consumption (city gas) has been as low as 15 cu. ft. per I.H.P. per hour, and the efficiency as high as 27% of the heating value of the gas. The principal improvement in practice has been the use of much higher compression of the working charge.

**Combustion of the Gas in the Otto Engine.**—John Imray, in discussion of Mr. Clerk's paper on Theory of the Gas-engine, says: The change which Mr. Otto introduced, and which rendered the engine a success, was that, instead of burning in the cylinder an explosive mixture of gas and air, he burned it in company with, and arranged in a certain way in respect of, a large volume of incombustible gas which was heated by it, and which diminished the speed of combustion. W. R. Bousfield, in the same discussion, says: In the Otto engine the charge varied from a charge which was an explosive mixture at the point of ignition to a charge which was merely an inert fluid near the piston. When ignition took place there was an explosion close to the point of ignition that was gradually communicated throughout the mass of the cylinder. As the ignition got farther away from the primary point of ignition the rate of transmission became slower, and if the engine were not worked too fast the ignition should gradually catch up to the piston during its travel, all the combustible gas being thus consumed. This theory of slow combustion is, however, disputed by Mr. Clerk, who holds that the whole quantity of combustible gas is ignited in an instant.

**Use of Carburetted Air in Gas-engines.**—Air passed over

gasoline or volatile petroleum spirit of low sp. gr., 0.65 to 0.70, liberates some of the gasoline, and the air thus saturated with vapor is equal in heating or lighting power to ordinary coal-gas. It may therefore be used as a fuel for gas-engines. Since the vapor is given off at ordinary temperatures gasoline is very explosive and dangerous, and should be kept in an underground tank out of doors. A defect in the use of carburetted air for gas-engines is that the more volatile products are given off first, leaving an oily residue which is often useless. Some of the substances in the oil that are taken up by the air are apt to form troublesome deposits and incrustations when burned in the engine cylinder.

**The Otto Gasoline-engine.** (*Eng'g News*, May 4, 1893.)—It is claimed that where but a small gasoline-engine is used and the gasoline bought at retail the liquid fuel will be on a par with a steam-engine using 6 lbs. of coal per horse-power per hour, and coal at \$3.50 per ton, and will besides save all the handling of the solid fuel and ashes, as well as the attendance for the boilers. As very few small steam-engines consume less than 6 lbs. of coal per hour, this is an exceptional showing for economy. At 8 cts. per gallon for gasoline and 1/10 gal. required per H.P. per hour, the cost per H.P. per hour will be 0.8 cent.

Gasoline-engines are coming into extensive use (1898). In these engines the gasoline is pumped from an underground tank, located at some distance outside the engine-room, and led through carefully soldered pipes to the working cylinder. In the combustion chamber the gasoline is sprayed into a current of air, by which it is vaporized. The mixture is then compressed and ignited by an electric spark. At no time does the gasoline come in contact with the air outside of the engine, nor is there any flame or burning gases outside of the cylinder.

**Naphtha-engines** are in use to some extent in small yachts and launches. The naphtha is vaporized in a boiler, and the vapor is used expansively in the engine-cylinder, as steam is used; it is then condensed and returned to the boiler. A portion of the naphtha vapor is used for fuel under the boiler. According to the circular of the builders, the Gas Engine and Power Co. of New York, a 2-H.P. engine requires from 3 to 4 quarts of naphtha per hour, and a 4-H.P. engine from 4 to 6 quarts. The chief advantages of the naphtha-engine and boiler for launches are the saving of weight and the quickness of operation. A 2-H.P. engine weighs 200 lbs., a 4-H.P. 300 lbs. It takes only about two minutes to get under headway. (*Modern Mechanism*, p. 270.)

**Hot-air (or Caloric) Engines.**—Hot-air engines are used to some extent, but their bulk is enormous compared with their effective power. For an account of the largest hot-air engine ever built (a total failure) see Church's *Life of Ericsson*. For theoretical investigation, see Rankine's *Steam-engine* and Rontgen's *Thermodynamics*. For description of constructions, see Appleton's *Cyc. of Mechanics* and *Modern Mechanism*, and Babcock on *Substitutes for Steam*, *Trans. A. S. M. E.*, vii., p. 693.

**Test of a Hot-air Engine** (Robinson).—A vertical double-cylinder (Caloric Engine Co.'s) 12 nominal H.P. engine gave 20.19 I.H.P. in the working cylinder and 11.38 I.H.P. in the pump, leaving 8.81 net I.H.P.; while the effective brake H.P. was 5.9, giving a mechanical efficiency of 67%. Consumption of coke, 3.7 lbs. per brake H.P. per hour. Mean pressure on pistons 15.37 lbs. per square inch, and in pumps 15.9 lbs., the area of working cylinders being twice that of the pumps. The hot air supplied was about 1160° F. and that rejected at end of stroke about 890° F.

**The Priestman Petroleum-engine.** (*Jour. Frank. Inst.*, Feb. 1893)—The following is a description of the operation of the engine: Any ordinary high-test (usually 150° test) oil is forced under air-pressure to an atomizer, where the oil is met by a current of air and broken up into atoms and sprayed into a mixer, where it is mixed with the proper proportion of supplementary air and sufficiently heated by the exhaust from the cylinder passing around this chamber. The mixture is then drawn by suction into the cylinder, where it is compressed by the piston and ignited by an electric spark, a governor controlling the supply of oil and air proportionately to the work performed. The burnt products are discharged through an exhaust-valve which is actuated by a cam. Part of the air supports the combustion of the oil, and the heat generated by the combustion of the oil expands the air that remains and the products resulting from the explosion, and thus develops its power from air that it takes in while running. In other words, the engine exerts its power by inhaling air, heating that air, and expelling the products of combustion when done with. In the largest engines only the 1/250 part of a pint of oil is used at any one time, and in

the smallest sizes the fuel is prepared in correct quantities varying from 1/7000 of a pint upward, according to whether the engine is running on light or full duty. The cycle of operations is the same as that of the Otto gas-engine.

**Trials of a 5-H.P. Priestman Petroleum-engine.** (Prof. W. C. Unwin, Proc. Inst. C. E. 1892.)—Cylinder, 8½ × 12 in., making normally 200 revs. per min. Two oils were used, Russian and American. The more important results were given in the following table:

	Trial V. Full Power.	Trial I. Full Power.	Trial IV. Full Power.	Trial II. Half Power.	Trial III. Light.
Oil used.....	Day- light.	Russo- lene.	Russo- lene.	Russo- lene.	Russo- lene.
Brake H.P .....	7.722	6.765	6.882	3.62	.....
I.H.P.....	9.369	7.408	8.332	4.70	0.889

**LOCOMOTIVES.**

**Resistance of Trains.**—Resistance due to Speed.—Various formulæ and tables for the resistance of trains at different speeds on a straight level track have been given by different writers. Among these are the following: By George R. Henderson (Proc. Engrs. Club of Phila., 1886):

$$R = 0.0015(1 + v^2 + 650),$$

in which *R* = resistance in lbs. per ton of 2240 lbs. and *v* = speed in miles per hour.

Speed in miles per hour:

5	10	15	20	25	30	35	40	45	50	55	60
Resistance in pounds per ton of 2000 lbs.:											
3.1	3.4	4.	4.8	5.8	7.1	8.6	10.2	12.1	14.3	16.8	19.2

By D. L. Barnes (*Eng. Mag.*), June, 1894 :

Speed, miles per hour .....	50	60	70	80	90	100
Resistance, pounds per gross ton..	12	12.4	13.5	15	17	20

By *Engineering News*, March 8, 1894 :

Resistance in lbs. per ton of 2000 lbs. =  $\frac{1}{4}v + 4$ .

Speed	.....	5	10	15	20	25	30	35	40	45	50	60	70	80	90	100
Resistance	..	3¼	4.5	5¾	7	8¼	9.5	10¾	12	13¼	14.5	17	19.5	22	24.5	27

By Baldwin Locomotive Works :

Resistance in lbs. per ton of 2000 lbs. =  $3 + v \div 6$ .

Speed	.....	5	10	15	20	25	30	35	40	45	50	55	60	70	80	90	100
Resistance	..	3.8	4.7	5.5	6.3	7.2	8	8.8	9.7	10.5	11.3	12.2	13	14.7	16.3	18	19.7

The resistance due to speed varies with the condition of the track, the number of cars in a train, and other conditions.

For tables showing that the resistance varies with the area exposed to the resistance and friction of the air per ton of loads, see Dashiell, *Trans. A. S. M. E.*, vol. xiii, p. 371.

P. H. Dudley (*Bulletin International Ry. Congress*, 1900, p. 1734) shows that the condition of the track is an important factor of train resistance which has not hitherto been taken account of. The resistance of heavy trains on the N. Y. Central R. R. at 20 miles an hour is only about 3½ lbs per ton on smooth 80-lb. 5½-in. rails. The resistance of an 80-car freight train, 60,000 lbs. per car, as given by indicator cards, at speeds between 15 and 25 miles per hour is represented by the formula  $R = 1 + \frac{1}{8}V$ , in which  $R$  = resistance in lbs. per ton and  $V$  = miles per hour.

*Resistance due to Grade.*—The resistance due to a grade of 1 ft. per mile is, per ton of 2000 lbs.,  $2000 \times \frac{1}{5280} = 0.3788$  lb. per ton, or if  $R_g$  = resistance in lbs. per ton due to grade and  $G$  = ft. per mile.  $R_g = 0.3788G$ .

If the grade is expressed as a percentage of the length, the resistance is 20 lbs per ton for each per cent of grade.

*Resistance due to Curves.*—Mr. Henderson gives the resistance due to curvature as 0.5 lb. per ton of 2000 lbs. per degree of the curve. (For definition of degrees of a railroad curve see p. 53.)

If  $c$  is the number of degrees,  $R_c$  the resistance in lbs. per ton, =  $0.5c$ . The Baldwin Locomotive Works take the approximate resistance due to each degree of curvature as that due to a straight grade of 1½ ft. per mile. This corresponds to  $R_c = 0.5682c$ .

*Resistance due to Acceleration.*—This may be calculated by means of the ordinary formulæ for acceleration, as follows :

Let  $V_1$  = velocity in ft. per second at the beginning of a mile run.

$V_2$  = velocity at the end of the mile.

$\frac{1}{2}(V_2 - V_1)$  = average velocity during the mile.

$T = 5280 \div \frac{1}{2}(V_2 - V_1)$  = time in seconds required to run the mile.

$w$  = weight of the train in lbs.  $W$  = weight in tons.

$f$  = resistance in lbs. due to acceleration =  $\frac{w}{g} \frac{(V_2 - V_1)}{T}$

$$= \frac{w}{32.2} \times \frac{(V_2 - V_1)^2}{10,560} = .005882W(V_2 - V_1)^2.$$

$S$  = increase of speed in miles per hour ;  $(V_2 - V_1)^2 = S^2 \times (22/15)^2$ .

$R_a$  = resistance in lbs. per ton =  $.01265S^2$ .

*Total Resistance.*—The total resistance in lbs. per ton of 2000 lbs. due to speed, to grade, to curves, and to acceleration is the sum of the resistances calculated above. Taking the Baldwin Locomotive Works' rules for speed and curvature, we have

$$Rt = \left(3 + \frac{v}{6}\right) + 0.3788G + 0.5682c + .01265S^2,$$

in which  $Rt$  is the resistance in lbs per ton of 2000 lbs.,  $v$  = speed in miles per hour,  $G$  = grade in ft. per mile  $c$  = degrees of curvature,  $S$  = rate of increase of speed in miles per hour in a run of one mile.

**Resistance due to Friction.**—In the above formula no account has been taken of the resistance to the friction of the working parts of the engine, nor to the friction of the engine and tender on curves due to the rigid wheel bases. No satisfactory formula can be given for these resistances. Mr. Henderson takes them as being proportional to the tractive power, so that, if the total tractive power be  $P$ , the effective tractive is  $uP$ ,

and the resistance  $(1 - u)P$ , the value of the coefficient  $u$  being probably about 0.8.

The Baldwin Locomotive Works in their "Locomotive Data" take the total resistance on a straight level track at slow speeds at from 6 to 10 lbs. per ton, and in a communication printed in the fourth edition (1898) of this Pocket-book, p. 1076, say: "We know that in some cases, for instance in mine construction, the frictional resistance has been shown to be as much as 60 lbs. per ton at slow speed. The resistance should be approximated to suit the conditions of each individual case, and the increased resistance due to speed added thereto."

Holmes on the Steam-engine, p. 142, says: "The frictional resistance to uniform motion of the whole train, including the engine and tender, is usually expressed by giving the direct pull in pounds necessary in order to propel each ton's weight of the train along a level line at slow speed. The pull varies with the condition of the line, the state of the surface of the rails, the state of the rolling stock, and the speed. If  $M$  be the speed in miles per hour, and  $T$  the weight of the train in tons [2240 lbs.] exclusive of engine and tender, the resistance to uniform motion may be expressed by the formula

$$R = [6 + 0.3(M - 10)T].$$

If  $T_1$  be the weight of the engine and tender, the corresponding resistance is

$$R_1 = [12 + 0.3(M - 10)T_1],$$

which expression includes the friction of the mechanism of the engine.

Holmes also says that a strong side wind by pressing the tires of the wheels against the rails may increase the frictional resistance of the train by as much as 20 per cent.

**Hauling Capacity due to Adhesion.**—The limit of the hauling capacity of a locomotive is the adhesion due to the weight on the driving wheels. Holmes gives the adhesion, in English practice, as equal to 0.15 of the load on the driving wheels in ordinary dry weather, but only 0.07 in damp weather or when the rails are greasy. In American practice it is generally taken as from 1/4 to 1/5 of the load on the drivers. The hauling capacity at slow speed on a track of different grades may be calculated by the following formula:

Let  $T$  = tons of 2000 lbs., locomotive and train, per 1000 lbs. load on drivers,  $a$  = the reciprocal of the coefficient of adhesion,  $g$  = the per cent of grade,  $R$  = the frictional resistance in lbs. per ton. Then  $T = \frac{1000 \div a}{R + 20g}$ .

From this formula the following table has been calculated :

Grade Per Cent,	0	0.5	1	1.5	2	2.5	3	3.5	4	5	6	7
Tons Hauling Capacity per 1000 lbs. Weight on Drivers.												
For $a = 4, R = 6..$	42	15.6	9.2	6.9	5.4	4.5	3.8	3.3	2.9	2.4	2.0	1.7
$a = 5, R = 8..$	25	11.1	7.2	5.3	4.2	3.4	2.9	2.6	2.3	1.9	1.6	1.4
$a = 5, R = 10..$	20	10.	6.7	5.	4.	3.3	2.9	2.5	2.2	1.8	1.5	1.3

**Tractive Power of a Locomotive.**—*Single Expansion.*

Let  $P$  = tractive power in lbs.

$p$  = average effective pressure in cylinder in lbs. per sq. in.

$S$  = stroke of piston in inches.

$d$  = diameter of cylinders in inches.

$D$  = diameter of driving-wheels in inches. Then

$$P = \frac{4\pi d^2 p S}{4\pi D} = \frac{d^2 p S}{D}$$

The average effective pressure can be obtained from an indicator-diagram, or by calculation, when the initial pressure and ratio of expansion are known, together with the other properties of the valve-motion. The subjoined table from "Auchincloss" gives the proportion of mean effective pressure to boiler-pressure above atmosphere for various proportions of cut-off.

Stroke, Cut off at—	M.E.P. (Boiler- pres. = 1).	Stroke, Cut off at—	(M.E.P. Boiler- pres. = 1).	Stroke, Cut off at—	M.E.P. (Boiler- pres. = 1).
.1	.15	.333 = $\frac{1}{3}$	.5 = $\frac{1}{2}$	.625 = $\frac{5}{8}$	.79
.125 = $\frac{1}{8}$	.2	.375 = $\frac{3}{8}$	.55	.666 = $\frac{2}{3}$	.82
.15	.24	.4	.57	.7	.85
.175	.28	.45	.62	.75 = $\frac{3}{4}$	.89
.2	.32	.5 = $\frac{1}{2}$	.67	.8	.93
.25 = $\frac{1}{4}$	.4	.55	.72	.875 = $\frac{7}{8}$	.98
.3	.46				

These values were deduced from experiments with an English locomotive by Mr. Gooch. As diagrams vary so much from different causes, this table will only fairly represent practical cases. It is evident that the cut-off must be such that the boiler will be capable of supplying sufficient steam at the given speed.

*Compound Locomotives.*—The Baldwin Locomotive Works give the following formulæ for compound engines of the Vaucrain four-cylinder type :

$$T = \frac{C^2S \times \frac{2}{3}P}{D} + \frac{c^2S \times \frac{1}{4}P}{D}.$$

$T$  = tractive power in lbs.

$C$  = diam. of high-pressure cylinder in ins.

$c$  = " " low " " "

$P$  = boiler-pressure in lbs.

$S$  = stroke of piston in ins.

$D$  = diam. of driving-wheels in ins.

For a two-cylinder or cross-compound engine it is only necessary to consider the high-pressure cylinder, allowing a sufficient decrease in boiler pressure to compensate for the necessary back-pressure. The formula is

$$T = \frac{C^2S \times \frac{2}{3}P}{D}.$$

**Efficiency of the Mechanism of a Locomotive.**—Frank C. Wagner (Proc. A. A. S., 1900, p. 140) gives an account of some dynamometer tests which indicate that in ordinary freight service the power used to drive the locomotive and tender and to overcome the friction of the mechanism is from 10% to 35% of the total power developed in the steam-cylinder. In one test the weight of the locomotive and tender was 16% of the total weight of the train, while the power consumed in the locomotive and tender was from 30% to 33% of the indicated horse-power.

**The Size of Locomotive Cylinders** is usually taken to be such that the engine will just overcome the adhesion of its wheels to the rails under favorable circumstances.

The adhesion is taken by a committee of the Am. Ry. Master Mechanics' Assn. as 0.25 of the weight on the drivers for passenger engines, 0.24 for freight, and 0.22 for switching engines ; and the mean effective pressure in the cylinder, when exerting the maximum tractive force, is taken at 0.85 of the boiler-pressure.

Let  $W$  = weight on drivers in lbs. ;  $P$  = tractive force in lbs., = say  $0.25W$  ;  $p_1$  = boiler-pressure in lbs. per sq. in. ;  $p$  = mean effective pressure, =  $0.85p_1$  ;  $d$  = diam. of cylinder,  $S$  = length of stroke, and  $D$  = diam. of driving-wheels, all in inches. Then

$$W = 4P = \frac{4d^2pS}{D} = \frac{4d^2 \times 0.85p_1S}{D}.$$

Whence 
$$d = 0.5 \sqrt{\frac{DW}{pS}} = 0.542 \sqrt{\frac{DW}{p_1S}}.$$

Von Borries's rule for the diameter of the low-pressure cylinder of a compound locomotive is  $d^2 = \frac{2ZD}{ph}$ ,

where  $d$  = diameter of l.p. cylinder in inches;  
 $D$  = diameter of driving-wheel in inches;  
 $p$  = mean effective pressure per sq. in., after deducting internal machine friction;  
 $h$  = stroke of piston in inches;  
 $Z$  = tractive force required, usually 0.14 to 0.16 of the adhesion.

The value of  $p$  depends on the relative volume of the two cylinders, and from indicator experiments may be taken as follows:

Class of Engine.	Ratio of Cylinder Volumes.	$p$ in percentage of Boiler-pressure.	$p$ for Boiler-pressure of 176 lbs.
Large-tender eng's	1 : 2 or 1 : 2.05	42	74
Tank-engines.....	1 : 2 or 1 : 2.2	40	71

**Horse-power of a Locomotive.**—For each cylinder the horse-power is  $H.P. = pLaN \div 33,000$ , in which  $p$  = mean effective pressure,  $L$  = stroke in feet,  $a$  = area of cylinder =  $\frac{1}{4}\pi d^2$ ,  $N$  = number of single strokes per minute,  $LN$  = piston speed, ft. per min. Let  $M$  = speed of train in miles per hour,  $S$  = length of stroke in inches, and  $D$  = diameter of driving-wheel in inches. Then  $LN = M \times 88 \times 2S \div \pi D$ . Whence for the two cylinders the horse-power is

$$\frac{2 \times p \times \frac{1}{4}\pi d^2 \times 176S \times M}{\pi D \times 33,000} = \frac{pd^2SM}{375D}.$$

**The Size of Locomotive Boilers.** (Forney's Catechism of the Locomotive.)—They should be proportioned to the amount of adhesive weight and to the speed at which the locomotive is intended to work. Thus a locomotive with a great deal of weight on the driving-wheels could pull a heavier load, would have a greater cylinder capacity than one with little adhesive weight, would consume more steam, and therefore should have a larger boiler.

The weight and dimensions of locomotive boilers are in nearly all cases determined by the limits of weight and space to which they are necessarily confined. It may be stated generally that *within these limits a locomotive boiler cannot be made too large*. In other words, boilers for locomotives should always be made as large as is possible under the conditions that determine the weight and dimensions of the locomotives. (See also Holmes on the Steam-engine, pp. 371 to 377 and 383 to 389, and the Report of the Am. Ry. M. M. Assn. for 1897, pp. 218 to 232.)

Holmes gives the following from English practice :

Evaporation, 9 to 12 lbs. of water from and at 212°.

Ordinary rate of combustion, 65 lbs. per sq. ft. of grate per hour.

Ratio of grate to heating surface, 1 : 60 to 90.

Heating surface per lb. of coal burnt per hour, 0.9 to 1.5 sq. ft.

**Qualities Essential for a Free-steaming Locomotive.**

(From a paper by A. E. Mitchell, read before the N. Y. Railroad Club; *Eng'g News*, Jan. 24, 1891.)—Square feet of boiler-heating surface for bituminous coal should not be less than 4 times the square of the diameter in inches of a cylinder 1 inch larger than the cylinder to be used. One tenth of this should be in the fire-box. On anthracite locomotives more heating-surface is required in the fire-box, on account of the larger grate-area required, but the heating-surface of the flues should not be materially decreased.

**Wootten's Locomotive.** (Clark's Steam-engine; see also Jour. Frank. Inst. 1891, and Modern Mechanism, p. 485.)—J. E. Wootten designed and constructed a locomotive boiler for the combustion of anthracite and lignite, though specially for the utilization as fuel of the waste produced in the mining and preparation of anthracite. The special feature of the engine is the fire-box, which is made of great length and breadth, extending clear over the wheels, giving a grate-area of from 64 to 85 sq. ft. The draught diffused over these large areas is so gentle as not to lift the fine particles of the fuel. A number of express-engines having this type of boiler are engaged on the fast trains between Philadelphia and Jersey City. The fire-box shell is 8 ft. 8 in. wide and 10 ft. 5 in. long; the fire-box is  $8 \times 9\frac{1}{2}$  ft., making 76 sq. ft. of grate-area. The grate is composed of bars and water-tubes alternately. The regular types of cast-iron shaking grates are also used. The height of the fire-box is only 2 ft. 5 in. above the grate. The grate is terminated by a bridge of fire-brick, beyond which a combustion-chamber, 27 in. long, leads to the flue-tubes, about 184 in number,  $1\frac{3}{4}$  in. diam. The cylinders are

21 in. diam., with a stroke of 22 inches. The driving-wheels, four-coupled, are 5 ft. 8 in. diam. The engine weighs 44 tons, of which 29 tons are on driving wheels. The heating-surface of the fire-box is 135 sq. ft., that of the flue-tubes is 982 sq. ft.; together, 1117 sq. ft., or 14.7 times the grate-area. Hauling 15 passenger-cars, weighing with passengers 360 tons, at an average speed of 42 miles per hour, over ruling gradients of 1 in 89, the engine consumes 62 lbs. of fuel per mile, or  $34\frac{1}{4}$  lbs. per sq. ft. of grate per hour.

**Grate-surface, Smoke-stacks, and Exhaust-nozzles for Locomotives.** (*Am. Mach.*, Jan. 8, 1891.)—For grate-surface for anthracite coal: Multiply the displacement in cubic feet of one piston during a stroke by 8.5; the product will be the area of the grate in square feet.

For bituminous coal: Multiply the displacement in feet of one piston during a stroke by  $6\frac{1}{2}$ ; the product will be the grate-area in square feet for engines with cylinders 12 in. in diameter and upwards. For engines with smaller cylinders the ratio of grate-area to piston-displacement should be  $7\frac{1}{2}$  to 1, or even more, if the design of the engine will admit this proportion.

The grate-areas in the following table have been found by the foregoing rules, and agree very closely with the average practice:

*Smoke-stacks.*—The internal area of the smallest cross-section of the stack should be  $1/17$  of the area of the grate in soft-coal-burning engines.

A. E. Mitchell, Supt. of Motive Power of the N. Y. L. E. & W. R. R., says that recent practice varies from this rule. Some roads use the same size of stack,  $13\frac{1}{2}$  in. diam. at throat, for all engines up to 20 in. diam. of cylinder.

The area of the orifices in the exhaust-nozzles depends on the quantity and quality of the coal burnt, size of cylinder, construction of stack, and the condition of the outer atmosphere. It is therefore impossible to give rules for computing the exact diameter of the orifices. All that can be done is to give a rule by which an approximate diameter can be found. The exact diameter can only be found by trial. Our experience leads us to believe that the area of each orifice in a double exhaust-nozzle should be equal to  $1/400$  part of the grate-surface, and for single nozzles  $1/200$  of the grate-surface. These ratios have been used in finding the diameters of the nozzles given in the following table. The same sizes are often used for either hard or soft coal-burners.

Size of Cylinders, in inches.	Grate-area for Anthracite Coal, in sq. in.	Grate-area for Bituminous Coal, in sq. in.	Diameter of Stacks, in inches.	Double Nozzles.	Single Nozzles.
				Diam. of Orifices, in inches.	Diam. of Orifices, in inches.
12 × 20	1591	1217	$9\frac{1}{2}$	2	$2\frac{13}{16}$
13 × 20	1873	1432	$10\frac{1}{2}$	$2\frac{1}{8}$	3

19 × 24	4810	3678	$16\frac{1}{2}$	$3\frac{7}{16}$	$4\frac{13}{16}$
20 × 24	5337	4081	$17\frac{1}{2}$	$3\frac{3}{8}$	$5\frac{1}{16}$

**Exhaust-nozzles in Locomotive Boilers.**—A committee of the Am. Ry. Master Mechanics' Assn. in 1890 reported that they had, after two years of experiment and research, come to the conclusion that, owing to the great diversity in the relative proportions of cylinders and boilers, together with the difference in the quality of fuel, any rule which does not recognize each and all of these factors would be worthless.

The committee was unable to devise any plan to determine the size of the exhaust-nozzle in proportion to any other part of the engine or boiler, and believes that the best practice is for each user of locomotives to adopt a nozzle that will make steam freely and fill the other desired conditions, best determined by an intelligent use of the indicator and a check on the fuel account. The conditions desirable are: That it must create draught enough on the fire to make steam, and at the same time impose the least possible amount of work on the pistons in the shape of back pressure. It should be large enough to produce a nearly uniform blast without lifting or tearing

the fire, and be economical in its use of fuel. The Annual Report of the Association for 1896 contains interesting data on this subject.

**Fire-brick Arches in Locomotive Fire-boxes.**—A committee of the Am. Ry. Master Mechanics' Assn. in 1890 reported strongly in favor of the use of brick arches in locomotive fire-boxes. They say: It is the unanimous opinion of all who use bituminous coal and brick arch, that it is most efficient in consuming the various gases composing black smoke, and by impeding and delaying their passage through the tubes, and mingling and subjecting them to the heat of the furnace, greatly lessens the volume ejected, and intensifies combustion, and does not in the least check but rather augments draught, with the consequent saving of fuel and increased steaming capacity that might be expected from such results. This in particular when used in connection with extension front.

**Size, Weight, Tractive Power, etc., of Different Sizes of Locomotives.** (J. G. A. Meyer. Modern Locomotive Construction. *Am. Mach.*, Aug. 8, 1885.)—The tractive power should not be more or less than the adhesion. In column 3 of each table the adhesion is given, and since the adhesion and tractive power are expressed by the same number of pounds, these figures are obtained by finding the tractive power of each engine, for this purpose always using the small diameter of driving-wheels given in column 2. The weight on drivers is shown in column 4, which is obtained by multiplying the adhesion by 5 for all classes of engines. Column 5 gives the weights on the trucks, and these are based upon observations. Thus, the weight on the truck for an eight-wheeled engine is about one half of that placed on the drivers.

For Mogul engines we multiply the total weight on drivers by the decimal .2, and the product will be the weight on the truck.

For ten-wheeled engines the total weight on the drivers, multiplied by the decimal .32, will be equal to the weight on the truck.

And lastly, for consolidation engines, the total weight on drivers multiplied by the decimal .16, will determine the weight on the truck.

In column 6 the total weight of each engine is given, which is obtained by adding the weight on the drivers to the weight on the truck. Dividing the

adhesion given in column 3 by  $7\frac{1}{2}$  gives the tons of 2000 lbs. that the engine is capable of hauling on a straight and level track, column 7, at slow speed.

The weight of engines given in these tables will be found to agree generally with the actual weights of locomotives recently built, although it must not be expected that these weights will agree in every case with the actual weights, because the different builders do not build the engines alike.

The actual weight on trucks for eight-wheeled or ten-wheeled engines will not differ much from those given in the tables, because these weights depend greatly on the difference between the total and rigid wheel-base, and these are not often changed by the different builders. The proportion between the rigid and total wheel-base is generally the same.

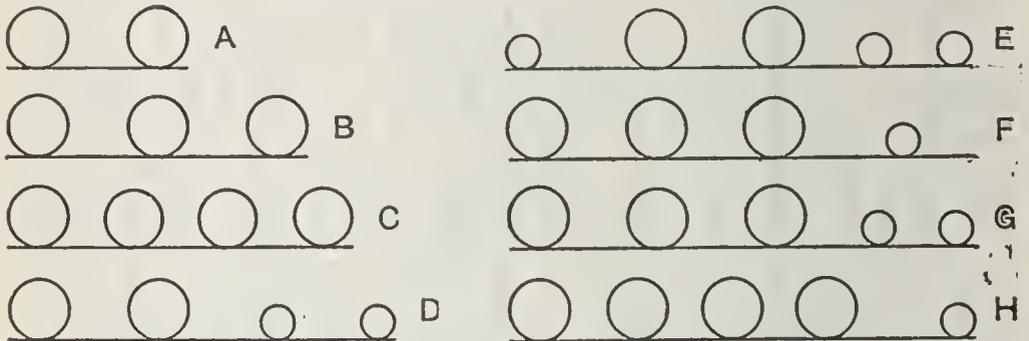

The rule for finding the tractive power is :

$$\frac{\left\{ \begin{array}{l} \text{Square of dia. of} \\ \text{piston in inches} \end{array} \right\} \times \left\{ \begin{array}{l} \text{Mean effect. steam} \\ \text{press. per sq. in.} \end{array} \right\}}{\text{Diameter of wheel in feet.}} \times \left\{ \begin{array}{l} \text{stroke} \\ \text{in feet} \end{array} \right\} = \text{tractive power.}$$

### Leading American Types of Locomotive for Freight and Passenger Service.

1. The eight-wheel or "American" passenger type, having four coupled driving-wheels and a four-wheeled truck in front.
2. The "ten-wheel" type, for mixed traffic, having six coupled drivers and a leading four-wheel truck.
3. The "Mogul" freight type, having six coupled driving-wheels and a pony or two-wheel truck in front.
4. The "Consolidation" type, for heavy freight service, having eight coupled driving-wheels and a pony truck in front.

Besides these there is a great variety of types for special conditions of service, as four-wheel and six-wheel switching-engines, without trucks; the Forney type used on elevated railroads, with four coupled wheels under the engine and a four-wheeled rear truck carrying the water-tank and fuel; locomotives for local and suburban service with four coupled driving-wheels, with a two-wheel truck front and rear, or a two-wheel truck front and a four-wheel truck rear, etc. "Decapod" engines for heavy freight service have ten coupled driving-wheels and a two-wheel truck in front.

**Classification of Locomotives** (Penna. R. R. Co., 1900).—Class A, two pairs of drivers and no truck. Class B, three pairs of drivers and no truck. Class C, four pairs of drivers and no truck. Class D, two pairs of drivers and four-wheel truck. Class E, two pairs of drivers, four-wheel truck, and trailing wheels. Class F, three pairs of driving-wheels and two-wheel truck. Class G, three pairs of drivers and four-wheel truck. Class H, four pairs of drivers and two-wheel truck. Class A is commonly called a "four-wheeler"; B, a "six-wheeler"; D, an "eight-wheeler," or "American" type; E, "Atlantic" type; F, "Mogul"; G, "ten-wheeler"; H, "Consolidation."

### Steam-distribution for High-speed Locomotives.

(C. H. Quereau, *Eng'g News*, March 8, 1894.)

**Balanced Valves.**—Mr. Philip Wallis, in 1886, when Engineer of Tests for the C. & Q. R. R., reported that while 6 H.P. was required to work unbalanced valves at 40 miles per hour, for the balanced valves 2.2 H.P. only was necessary.

*Effect of Speed on Average Cylinder-pressure.*—Assume that a locomotive has a train in motion, the reverse lever is placed in the running notch, and the track is level; by what is the maximum speed limited? The resistance of the train and the load increase, and the power of the locomotive decreases with increasing speed till the resistance and power are equal, when the speed becomes uniform. The power of the engine depends on the average pressure in the cylinders. Even though the cut-off and boiler-pressure remain the same, this pressure decreases as the speed increases; because of the higher piston-speed and more rapid valve-travel the steam has a shorter time in which to enter the cylinders at the higher speed. The following table, from indicator-cards taken from a locomotive at varying speeds, shows the decrease of average pressure with increasing speed:

Miles per hour. ....	46	51	51	53	54	57	60	66
Speed, revolutions. ....	224	248	248	258	263	277	292	321
Average pressure per sq. in.:								
Actual. ....	51.5	44.0	47.3	43.0	41.3	42.5	37.3	36.3
Calculated. ....	46.5	46.5	44.7	43.8	41.6	39.5	35.9	

The "average pressure calculated" was figured on the assumption that the mean effective pressure would decrease in the same ratio that the speed increased. The main difference lies in the higher steam-line at the lower speeds, and consequent higher expansion-line, showing that more steam entered the cylinder. The back pressure and compression-lines agree quite closely for all the cards, though they are slightly better for the slower speeds. That the difference is not greater may safely be attributed to the large exhaust-ports, passages, and exhaust tip, which is 5 in. diameter. These are matters of great importance for high speeds.

*Boiler-pressure.*—Assuming that the train resistance increases as the speed after about 20 miles an hour is reached, that an average of 50 lbs. per sq. in. is the greatest that can be realized in the cylinders of a given engine at 40 miles an hour, and that this pressure furnishes just sufficient power to keep the train at this speed, it follows that, to increase the speed to 50 miles, the mean effective pressure must be increased in the same proportion. To increase the capacity for speed of any locomotive its power must be increased, and at least by as much as the speed is to be increased. One way to accomplish this is to increase the boiler-pressure. That this is generally realized, is shown by the increase in boiler-pressure in the last ten years. For twenty-three single-expansion locomotives described in the railway journals this year the steam-pressures are as follows: 3, 160 lbs.; 4, 165 lbs.; 2, 170 lbs.; 13, 180 lbs.; 1, 190 lbs.

*Valve-travel.*—An increased average cylinder-pressure may also be obtained by increasing the valve-travel without raising the boiler-pressure, and better results will be obtained by increasing both. The longer travel gives a higher steam-pressure in the cylinders, a later exhaust-opening, later exhaust-closure, and a larger exhaust-opening—all necessary for high speeds and economy. I believe that a 20-in. port and 6½-in. (or even 7-in.) travel could be successfully used for high-speed engines, and that frequently by so doing the cylinders could be economically reduced and the counter-balance lightened. Or, better still, the diameter of the drivers increased, securing lighter counterbalance and better steam-distribution.

*Size of Drivers.*—Economy will increase with increasing diameter of drivers, provided the work at average speed does not necessitate a cut-off longer than one fourth the stroke. The piston-speed of a locomotive with 62-in. drivers at 55 miles per hour is the same as that of one with 68-in. drivers at 61 miles per hour.

*Steam-ports.*—The length of steam-ports ranges from 15 in. to 23 in., and has considerable influence on the power, speed, and economy of the locomotive. In cards from similar engines the steam-line of the card from the engine with 23-in. ports is considerably nearer boiler-pressure than that of the card from the engine with 17¼-in. ports. That the higher steam-line is due to the greater length of steam-port there is little room for doubt. The 23-in. port produced 531 H.P. in an 18½-in. cylinder at a cost of 23.5 lbs. of indicated water per I.H.P. per hour. The 17¼-in. port, 424 H.P., at the rate of 22.9 lbs. of water, in a 19-in. cylinder.

*Allen Valves.*—There is considerable difference of opinion as to the advantage of the Allen ported-valve (See *Eng. News*, July 6, 1893.)

*Speed of Railway Trains.*—In 1834 the average speed of trains on the Liverpool and Manchester Railway was twenty miles an hour; in 1838 it

was twenty-five miles an hour. But by 1840 there were engines on the Great Western Railway capable of running fifty miles an hour with a train, and eighty miles an hour without. (Trans. A. S. M. E., vol. xiii., 363.)

The limitation to the increase of speed of heavy locomotives seems at present to be the difficulty of counterbalancing the reciprocating parts. The unbalanced vertical component of the reciprocating parts causes the pressure of the driver on the rail to vary with every revolution. Whenever the speed is high, it is of considerable magnitude, and its change in direction is so rapid that the resulting effect upon the rail is not inappropriately called a "hammer blow." Heavy rails have been kinked, and bridges have been shaken to their fall under the action of heavily balanced drivers revolving at high speeds. The means by which the evil is to be overcome has not yet been made clear. See paper by W. F. M. Goss, Trans. A. S. M. E., vol. xvi.

Engine No. 999 of the New York Central Railroad ran a mile in 32 seconds equal to 112 miles per hour, May 11, 1893.

$$\begin{aligned} \text{Speed in miles} \left. \begin{array}{l} \text{per hour} \end{array} \right\} &= \frac{\text{circum. of driving-wheels in in.} \times \text{no. of rev. per min.} \times 60}{63,360} \\ &= \frac{\text{diam. of driving-wheels in in.} \times \text{no. of rev. per min.} \times .003}{(\text{approximate, giving result } 8/10 \text{ of 1 per cent too great})} \end{aligned}$$

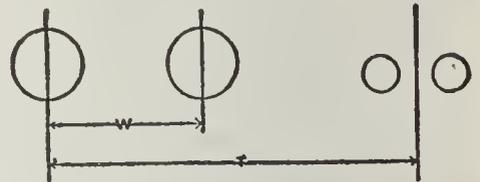

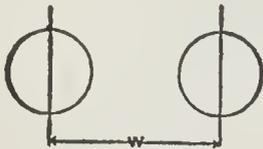

**Formulae for Curves.** (Baldwin Locomotive Works.)

Approximate Formula for Radius.

$$R = \frac{.7646W}{2P}.$$

Approximate Formula for Swing.

$$\frac{WT}{2R} = S.$$

$R$  = radius of min. curve in feet.  
 $P$  = play of driving-wheels in decimals of 1 ft.  
 $W$  = rigid wheel-base in feet.

$W$  = rigid wheel base.  
 $T$  = total " "  
 $R$  = radius of curve.  
 $S$  = swing on each side of centre."

**Performance of a High-speed Locomotive.**—The Baldwin compound locomotive No. 1027, on the Phila. & Atlantic City Ry., in July and August, 1897, made a record of which the following is a summary:

On July 2d a train was placed in service scheduled to make the run between the terminal cities in 1 hour. Allowing 3 minutes for ferry from Philadelphia to Camden, the time for the 55½ miles from the latter point to Atlantic City was 52 minutes, or at the rate of 64 miles per hour. Owing to the inability of the ferry-boats to reach Camden on time, the train always left late, the average detention being upwards of 2 minutes. This loss was invariably made up, the train arriving at Atlantic City ahead of time, 2 minutes on an average, every day. For the 52 days the train ran, from July 2d to August 31st, the average time consumed on the run was 48 minutes, equivalent to a uniform rate of speed from start to stop of 69 miles per hour. On July 14th the run from Camden to Atlantic City was made in 46½ min., an average of 71.6 miles per hour for the total distance. On 22 days the train consisted of 5 cars and on 30 days it was made up of 6, the weight of cars being as follows: combination car, 57,200 lbs.; coaches, each, 59,200 lbs.; Pullman car, 85,500 lbs.

The general dimensions of the locomotive are as follows: cylinders, 13 and 22 x 26 in.; height of drivers, 84¼ in.; total wheel-base, 26 ft. 7 in.; driving-wheel base, 7 ft. 3 in.; length of tubes, 13 ft.; diameter of boiler, 58¾ in.; diameter of tubes, 1¾ in.; number of tubes, 278; length of fire-box, 113¾ in.; width of fire-box, 96 in.; heating-surface of fire-box, 136.4 sq. ft.; heating-surface of tubes, 1614.9 sq. ft.; total heating-surface, 1835.1 sq. ft.; tank capacity, 4000 gallons; boiler-pressure, 200 lbs. per sq. in.; total weight of engine and tender, 227,000 lbs.; weight on drivers (about), 78,600 lbs.

**Locomotive Link Motion.**—Mr. F. A. Halsey, in his work on "Locomotive Link Motion," 1898, shows that the location of the eccentric-rod pins back of the link-arc and the angular vibrations of the eccentric-rods introduce two errors in the motion which are corrected by the angular

vibration of the connecting-rod and by locating the saddle-stud back of the link-arc. He holds that it is probable that the opinions of the critics of the locomotive link motion are mistaken ones, and that it comes little short of all that can be desired for a locomotive valve motion. The increase of lead from full to mid gear and the heavy compression at mid gear are both advantages and not defects. The cylinder problem of a locomotive is entirely different from that of a stationary engine. With the latter the problem is to determine the size of the cylinder and the distribution of steam to drive economically a given load at a given speed. With locomotives the cylinder is made of a size which will start the heaviest train which the adhesion of the locomotive will permit, and the problem then is to utilize that cylinder to the best advantage at a greatly increased speed, but under a greatly reduced mean effective pressure.

Negative lead at full gear has been used in the recent practice of some railroads. The advantages claimed are an increase in the power of the engine at full gear, since positive lead offers resistance to the motion of the piston; easier riding; reduced frequency of hot bearings; and a slight gain in fuel economy. Mr. Halsey gives the practice as to lead on several roads as follows, showing great diversity:

	Full Gear Forward, in.	Full Gear Back, in.	Reversing Gear, in.
New York, New Haven & Hartford .....	1/16 pos.	1/4 neg.	1/4 pos.
Maine Central .....	0	1/4 neg.	.....
Illinois Central .....	1/32 pos.	.....	abt. 3/16
Lake Shore .....	1/16 neg.	9/64 neg.	5/16 pos.
Chicago Great Western .....	0	0	3/16 to 9/16
Chicago & Northwestern .....	3/16 neg.	.....	1/4 pos.

The link-chart of a locomotive built in 1897 by the Schenectady Locomotive Works for the Northern Pacific Ry. is as follows:

Lead.		Valve Open.		Cut-off.	
Forward Stroke, in.	Rearward Stroke, in.	Forward Stroke, in.	Rearward Stroke, in.	Forward Stroke, in.	Rearward Stroke, in.
- 1/8	- 1/8	1 7/8	1 7/8	22 9/16	22 5/8
- 1/32	- 1/32	1 7/16	1 7/16	21	21
+ 1/32	+ 1/32	1 1/16	1 1/16	19	19
3/32	3/32	23/32	23/32	16	16

Cylinders 20 x 26 in., driving-wheels 69 in., six coupled wheels, main rods 126 1/2 in., radius of link 40 in., lap 1 1/8 in., travel 6 in., Allen valve.

### DIMENSIONS OF SOME LARGE AMERICAN LOCOMOTIVES, 1893.

The four locomotives described below were exhibited at the Chicago Exposition in 1893. The dimensions are from *Engineering News*, June, 1893. The first, or Decapod engine, has ten-coupled driving-wheels. It is one of the heaviest and most powerful engines ever built for freight service. The Philadelphia & Reading engine is a new type for passenger service, with four-coupled drivers. The Rhode Island engine has six drivers, with a 4-wheel leading truck and a 2-wheel trailing truck. These three engines have all compound cylinders. The fourth is a simple engine, of the standard American 8-wheel type, 4 driving-wheels, and a 4-wheel truck in front. This engine holds the world's record for speed (1893) for short distances, having run a mile in 32 seconds.

**Dimensions of Some American Locomotives.**—The table on page 861 is condensed from one given by D. L. Barnes, in his paper on "Distinctive Features and Advantages of American Locomotive Practice," Trans. A.S.C.E., 1893. The formula from which column marked "Ratio of cylinder-power to weight available for adhesion" is calculated as follows:

$$\frac{2 \times \text{cylinder area} \times \text{boiler-pressure} \times \text{stroke}}{\text{Weight on drivers} \times \text{diameter of driving-wheel}}$$

(Ratio of cylinder-power of compound engines cannot be compared with that of the single-expansion engines.)

Where the boiler-pressure could not be determined from the description of the locomotives, as given by the builders and operators of the locomotives, it has been assumed to be 160 lbs. per sq. in. above the atmosphere.

For compound locomotives the figures in the last column of ratios are based on the capacity of the low-pressure cylinders only, the volume of the high-pressure being omitted. This has been done for the purpose of comparison, and because there is no accurate simple way of comparing the cylinder-power of single-expansion and compound locomotives.

**Dimensions of Standard Locomotives on the N. Y. C. & H. R. R. and Penna. R. R., 1882 and 1893.**

**Indicated Water Consumption of Single and Compound Locomotive Engines at Varying Speeds.**

C. H. Quereau, *Eng'g News*, March 8, 1894.

Two-cylinder Compound.			Single-expansion.		
Revolutions.	Speed, miles per hour.	Water per I.H.P. per hour.	Revolutions.	Miles per Hour.	Water.
100 to 150	21 to 31	18.33 lbs.	151	31	21.70
150 " 200	31 " 41	18.9 "	219	45	20.91
200 " 250	41 " 51	19.7 "	253	52	20.52
250 " 275	51 " 56	21.4 "	307	63	20.23
			321	66	20.01

It appears that the compound engine is the more economical at low speeds, the economy decreasing as the speed increases, and that the single engine increases in economy with increase of speed within ordinary limits, becoming more economical than the compound at speeds of more than 50 miles per hour.

The C., B. & Q. two-cylinder compound, which was about 30% less economical than simple engines of the same class when tested in passenger service, has since been shown to be 15% more economical in freight service

than the best single-expansion engine, and 29% more economical than the average record of 40 simple engines of the same class on the same division.

**Indicator-tests of a Locomotive at High Speed.** (*Locomotive Eng'g*, June, 1893).—Cards were taken by Mr. Angus Sinclair on the locomotive drawing the Empire State Express.

RESULTS OF INDICATOR-DIAGRAMS.

Card No.	Revs.	Miles per hour.	I.H.P.	Card No.	Revs.	Miles per hour.	I.H.P.
1	160	37.1	648.3	7	304	70.5	977

4	250	58	891	10	304	70.5	1,059
5	260	60	960	11	340	78.9	1,120
6	298	69	983	12	310	71.9	1,026

The locomotive was of the eight-wheel type, built by the Schenectady Locomotive Works, with 19 × 24 in. cylinders, 78-in. drivers, and a large boiler and fire-box. Details of important dimensions are as follows: Heating-surface of fire-box, 150.8 sq. ft.; of tubes, 1670.7 sq. ft.; of boiler, 1821.5 sq. ft. Grate area, 27.3 sq. ft. Fire-box: length, 8 ft.; width, 3 ft. 4 7/8 in. Tubes, 268; outside diameter, 2 in. Ports: steam, 18 × 1 1/4 in.; exhaust, 18 × 2 3/4 in. Valve-travel, 5 1/2 in. Outside lap, 1 in.; inside lap, 1/64 in. Journals: driving-axle, 8 1/2 × 10 1/2 in.; truck-axle, 6 × 10 in.

The train consisted of four coaches, weighing, with estimated load, 340,000 lbs. The locomotive and tender weighed in working order 200,000 lbs., making the total weight of the train about 270 tons. During the time that the engine was first lifting the train into speed diagram No. 1 was taken. It shows a mean cylinder-pressure of 59 lbs. According to this, the power exerted on the rails to move the train is 6553 lbs., or 24 lbs. per ton. The speed is 37 miles an hour. When a speed of nearly 60 miles an hour was reached the average cylinder-pressure is 40.7 lbs., representing a total traction force of 4520 lbs., without making deductions for internal friction. If we deduct 10% for friction, it leaves 15 lbs. per ton to keep the train going at the speed named. Cards 6, 7, and 8 represent the work of keeping the train running 70 miles an hour. They were taken three miles apart, when the speed was almost uniform. The average cylinder-pressure for the three cards is 47.6 lbs. Deducting 10% again for friction, this leaves 17.6 lbs. per ton as the power exerted in keeping the train up to a velocity of 70 miles. Throughout the trip 7 lbs. of water were evaporated per lb. of coal. The work of pulling the train from New York to Albany was done on a coal consumption of about 3 1/8 lbs. per H.P. per hour. The highest power recorded was at the rate of 1120 H.P.

**Locomotive-testing Apparatus at the Laboratory of Purdue University.** (W. F. M. Goss, *Trans. A. S. M. E.*, vol. xiv. 826.)—The locomotive is mounted with its drivers upon supporting wheels which are carried by shafts turning in fixed bearings, thus allowing the engine to be run without changing its position as a whole. Load is supplied by four friction-brakes fitted to the supporting shafts and offering resistance to the turning of the supporting wheels. Traction is measured by a dynamometer attached to the draw-bar. The boiler is fired in the usual way, and an exhaust-blower above the engine, but not in pipe connection with it, carries off all that may be given out at the stack.

*A Standard Method of Conducting Locomotive-tests* is given in a report by a Committee of the A. S. M. E. in vol. xiv. of the *Transactions*, page 1312.

**Waste of Fuel in Locomotives.**—In American practice economy of fuel is necessarily sacrificed to obtain greater economy due to heavy train-loads. D. L. Barnes, in *Eng. Mag.*, June, 1894, gives a diagram showing the reduction of efficiency of boilers due to high rates of combustion, from which the following figures are taken:

Lbs. of coal per sq. ft. of grate per hour.....	12	40	80	120	160	200
Per cent efficiency of boiler.....	80	75	67	59	51	43

A rate of 12 lbs. is given as representing stationary-boiler practice, 40 lbs. is English locomotive practice, 120 lbs. average American, and 200 lbs. maximum American, locomotive practice.

**Advantages of Compounding.**—Report of a Committee of the American Railway Master Mechanics' Association on Compound Locomotives (*Am. Mach.*, July 3, 1890) gives the following summary of the advantages gained by compounding: (a) It has achieved a saving in the fuel burnt averaging 18% at reasonable boiler-pressures, with encouraging possibilities

of further improvement in pressure and in fuel and water economy. (b) It has lessened the amount of water (dead weight) to be hauled, so that (c) the tender and its load are materially reduced in weight. (d) It has increased the possibilities of speed far beyond 60 miles per hour, without unduly straining the motion, frames, axles, or axle-boxes of the engine. (e) It has increased the haulage-power at full speed, or, in other words, has increased the continuous H.P. developed, per given weight of engine and boiler. (f) In some classes has increased the starting-power. (g) It has materially lessened the slide-valve friction per H.P. developed. (h) It has equalized or distributed the turning force on the crank-pin, over a longer portion of its path, which, of course, tends to lengthen the repair life of the engine. (i) In the two-cylinder type it has decreased the oil consumption, and has even done so in the Woolf four-cylinder engine. (j) Its smoother and steadier draught on the fire is favorable to the combustion of all kinds of soft coal; and the sparks thrown being smaller and less in number, it lessens the risk to property from destruction by fire. (k) These advantages and economies are gained without having to improve the man handling the engine, less being left to his discretion (or careless indifference) than in the simple engine. (l) Valve-motion, of every locomotive type, can be used in its best working and most effective position. (m) A wider elasticity in locomotive design is permitted; as, if desired, side-rods can be dispensed with, or articulated engines of 100 tons weight, with independent trucks, used for sharp curves on mountain service, as suggested by Mallet and Brunner.

Of 27 compound locomotives in use on the Phila. and Reading Railroad (in 1892), 12 are in use on heavy mountain grades, and are designed to be the equivalent of 22 × 24 in. simple consolidations; 10 are in somewhat lighter service and correspond to 20 × 24 in. consolidations; 5 are in fast passenger service. The monthly coal record shows:

Class of Engine.	No.	Gain in Fuel Economy.
Mountain locomotives. ....	12	25% to 30%
Heavy freight service.....	10	12% to 17%
Fast passenger .....	5	9% to 11%

(Report of Com. A. R. M. M. Assn. 1892.) For a description of the various types of compound locomotive, with discussion of their relative merits, see paper by A. Von Borries, of Germany, The Development of the Compound Locomotive, Trans. A. S. M. E. 1893, vol. xiv., p. 1172.

**Counterbalancing Locomotives.**—The following rules, adopted by different locomotive-builders, are quoted in a paper by Prof. Lanza (Trans. A. S. M. E., x. 302):

A. "For the main drivers, place opposite the crank-pin a weight equal to one half the weight of the back end of the connecting-rod plus one half the weight of the front end of the connecting-rod, piston, piston-rod, and cross-head. For balancing the coupled wheels, place a weight opposite the crank-pin equal to one half the parallel rod plus one half of the weights of the front end of the main-rod, piston, piston-rod, and cross-head. The centres of gravity of the above weights must be at the same distance from the axles as the crank-pin."

B. The rule given by D. K. Clark: "Find the separate revolving weights of crank-pin boss, coupling-rods, and connecting-rods for each wheel, also the reciprocating weight of the piston and appendages, and one half the connecting-rod, divide the reciprocating weight equally between each wheel and add the part so allotted to the revolving weight on each wheel: the sums thus obtained are the weights to be placed opposite the crank-pin, and at the same distance from the axis. To find the counterweight to be used when the distance of its centre of gravity is known, multiply the above weight by the length of the crank in inches and divide by the given distance." This rule differs from the preceding in that the same weight is placed in each wheel.

$$S \times \left( w - \frac{w}{f} \right)$$

C. " $W = \frac{S \times \left( w - \frac{w}{f} \right)}{G}$ , in which  $S$  = one half the stroke,  $G$  = distance

from centre of wheel to centre of gravity in counterbalance,  $w$  = weight at crank-pin to be balanced,  $W$  = weight in counterbalance,  $f$  = coefficient of friction so called, = 5 in ordinary practice. The reciprocating weight is found by adding together the weights of the piston, piston-rod, cross-head, and one half of the main rod. The revolving weight for the main wheel is found by adding together the weights of the crank-pin hub, crank-pin, one

half of the main rod, and one half of each parallel-rod connecting to this wheel; to this add the reciprocating weight divided by the number of wheels. The revolving weight for the remainder of the wheels is found in the same manner as for the main wheel, except one half of the main rod is not added. The weight of the crank-pin hub and the counterbalance does not include the weight of the spokes, but of the metal inclosing them. This calculation is based for one cylinder and its corresponding wheels."

D. "Ascertain as nearly as possible the weights of crank-pin, additional weight of wheel boss for the same, add side rod, and main connections, piston-rod and head, with cross-head on one side: the sum of these multiplied by the distance in inches of the centre of the crank-pin from the centre of the wheel, and divided by the distance from the centre of the wheel to the common centre of gravity of the counterweights, is taken for the total counterweight for that side of the locomotive which is to be divided among the wheels on that side."

E. "Balance the wheels of the locomotive with a weight equal to the weights of crank-pin, crank-pin hub, main and parallel rods, brasses, etc., plus two thirds of the weight of the reciprocating parts (cross-head, piston and rod and packing)."

F. "Balance the weights of the revolving parts which are attached to each wheel with exactness, and divide equally two thirds of the weights of the reciprocating parts between all the wheels. One half of the main rod is computed as reciprocating, and the other as revolving weight."

See also articles on Counterbalancing Locomotives, in *R. R. & Eng. Jour.*, March and April, 1890; Trans. A. S. M. E., vol. xvi, 305; and Trans. Am. Ry. Master Mechanics' Assn., 1897. W. E. Dalby's book [on the "Balancing of Engines" (Longmans, Green & Co., 1902) contains a very full discussion of this subject.

#### **Maximum Safe Load for Steel Tires on Steel Rails.**

(A. S. M. E., vii., p. 786.)—Mr. Chanute's experiments led to the deduction that 12,000 lbs. should be the limit of load for any one driving-wheel. Mr. Angus Sinclair objects to Mr. Chanute's figure of 12,000 lbs., and says that a locomotive tire which has a light load on it is more injurious to the rail than one which has a heavy load. In English practice 8 and 10 tons are safely used. Mr. Oberlin Smith has used steel castings for cam-rollers 4 in. diam. and 3 in. face, which stood well under loads of from 10,000 to 20,000 lbs. Mr. C. Shaler Smith proposed a formula for the rolls of a pivot-bridge which may be reduced to the form:  $\text{Load} = 1760 \times \text{face} \times \sqrt{\text{diam.}}$ , all in lbs. and inches.

See dimensions of some large American locomotives on pages 860 and 861. On the "Decapod" the load on each driving-wheel is 17,000 lbs., and on "No. 999," 21,000 lbs.

#### **Narrow-gauge Railways in Manufacturing Works.—**

A tramway of 18 inches gauge, several miles in length, is in the works of the Lancashire and Yorkshire Railway. Curves of 13 feet radius are used. The locomotives used have the following dimensions (Proc. Inst. M. E., July, 1888): The cylinders were 5 in. diameter with 6 in. stroke, and 2 ft.  $3\frac{1}{4}$  in. centre to centre. The wheels were  $16\frac{1}{4}$  in. diameter, the wheel-base 2 ft. 9 in.; the frame 7 ft.  $4\frac{1}{4}$  in. long, and the extreme width of the engine 3 feet. The boiler, of steel, 2 ft. 3 in. outside diameter and 2 ft. long between tube-plates, containing 55 tubes of  $1\frac{3}{8}$  in. outside diameter; the fire-box, of iron and cylindrical, 2 ft. 3 in. long and 17 in. inside diameter. The heating-surface 10.42 sq. ft. in the fire-box and 36.12 in the tubes, total 46.54 sq. ft.; the grate-area, 1.78 sq. ft.; capacity of tank,  $26\frac{1}{2}$  gallons; working-pressure, 170 lbs. per sq. in.; tractive power, say, 1412 lbs., or 9.22 lbs. per lb. of effective pressure per sq. in. on the piston. Weight, when empty, 2.80 tons; when full and in working order, 3.19 tons.

For description of a system of narrow-gauge railways for manufactories, see circular of the C. W. Hunt Co., New York.

**Light Locomotives.**—For dimensions of light locomotives used for mining, etc., and for much valuable information concerning them, see catalogue of H. K. Porter & Co., Pittsburgh.

**Petroleum-burning Locomotives.** (From Clark's Steam-engine.)—The combustion of petroleum refuse in locomotives has been successfully practised by Mr. Thos. Urquhart, on the Grazi and Tsaritsin Railway, Southeast Russia. Since November, 1884, the whole stock of 143 locomotives under his superintendence has been fired with petroleum refuse. The oil is injected from a nozzle through a tubular opening in the back of the fire-box, by means of a jet of steam, with an induced current of air,

A brickwork cavity or "regenerative or accumulative combustion-chamber" is formed in the fire-box, into which the combined current breaks as spray against the rugged brickwork slope. In this arrangement the brickwork is maintained at a white heat, and combustion is complete and smokeless. The form, mass, and dimensions of the brickwork are the most important elements in such a combination.

Compressed air was tried instead of steam for injection, but no appreciable reduction in consumption of fuel was noticed.

The heating-power of petroleum refuse is given as 19,832 heat-units, equivalent to the evaporation of 20.53 lbs. of water from and at 212° F., or to 17.1 lbs. at 8½ atmospheres, or 125 lbs. per sq. in., effective pressure. The highest evaporative duty was 14 lbs. of water under 8½ atmospheres per lb. of the fuel, or nearly 82% efficiency.

There is no probability of any extensive use of petroleum as fuel for locomotives in the United States, on account of the unlimited supply of coal and the comparatively limited supply of petroleum. Texas oil is now (1902) used in locomotives of the Southern Pacific Railway.

**Fireless Locomotive.**—The principle of the Franco locomotive is that it depends for the supply of steam on its spontaneous generation from a body of heated water in a reservoir. As steam is generated and drawn off the pressure falls; but by providing a sufficiently large volume of water heated to a high temperature, at a pressure correspondingly high, a margin of surplus pressure may be secured, and means may thus be provided for supplying the required quantity of steam for the trip.

The fireless locomotive designed for the service of the Metropolitan Railway of Paris has a cylindrical reservoir having segmental ends, about 5 ft. 7 in. in diameter, 26¼ ft. in length, with a capacity of about 630 cubic feet. Four fifths of the capacity is occupied by water, which is heated by the aid of a powerful jet of steam supplied from stationary boilers. The water is heated until equilibrium is established between the boilers and the reservoir. The temperature is raised to about 390° F., corresponding to 225 lbs. per sq. in. The steam from the reservoir is passed through a reducing-valve, by which the steam is reduced to the required pressure. It is then passed through a tubular superheater situated within the receiver at the upper part, and thence through the ordinary regulator to the cylinders. The exhaust-steam is expanded to a low pressure, in order to obviate noise of escape. In certain cases the exhaust-steam is condensed in closed vessels, which are only in part filled with water. In the upper free space a pipe is placed, into which the steam is exhausted. Within this pipe another pipe is fixed, perforated, from which cold water is projected into the surrounding steam, so as to effect the condensation as completely as may be. The heated water falls on an inclined plane, and flows off without mixing with the cold water. The condensing water is circulated by means of a centrifugal pump driven by a small three-cylinder engine.

In working off the steam from a pressure of 225 lbs. to 67 lbs., 530 cubic feet of water at 390° F. is sufficient for the traction of the trains, for working the circulating-pump for the condensers, for the brakes, and for electric-lighting of the train. At the stations the locomotive takes from 2200 to 3300 lbs. of steam—nearly the same as the weight of steam consumed during the run between two consecutive charging stations. There is 210 cubic feet of condensing water. Taking the initial temperature at 60° F., the temperature rises to about 180° F. after the longest runs underground.

The locomotive has ten wheels, on a base 24 ft. long, of which six are coupled, 4½ ft. in diameter. The extreme wheels are on radial axles. The cylinders are 23½ in. in diameter, with a stroke of 23½ in.

The engine weighs, in working order, 53 tons, of which 36 tons are on the coupled wheels. The speed varies from 15 miles to 25 miles per hour. The trains weigh about 140 tons.

**Compressed-air Locomotives.**—For an account of the Mekarski system of compressed-air locomotives see page 510 *ante*.

## SHAFTING.

(See also TORSIONAL STRENGTH; also SHAFTS OF STEAM-ENGINES.)

For diameters of shafts to resist torsional strains only. Molesworth gives  $d = \sqrt[3]{\frac{Pl}{K}}$ , in which  $d$  = diameter in inches,  $P$  = twisting force in pounds applied at the end of a lever-arm whose length is  $l$  in inches,  $K$  = a coefficient whose values are, for cast iron 1500, wrought iron 1700, cast steel 3200, gun-bronze 460, brass 425, copper 380, tin 220, lead 170. The value given for cast steel probably applies only to high-carbon steel.

Thurston gives:

For head shafts well supported against springing (bearings close to pulleys or gears):	{	$\text{H.P.} = \frac{d^3 R}{125}; d = \sqrt[3]{\frac{125 \text{ H.P.}}{R}}, \text{ for iron;}$ $\text{H.P.} = \frac{d^3 R}{75}; d = \sqrt[3]{\frac{75 \text{ H.P.}}{R}}, \text{ for cold-rolled iron.}$
For line shafting, hangers 8 ft. apart:	{	$\text{H.P.} = \frac{d^3 R}{90}; d = \sqrt[3]{\frac{90 \text{ H.P.}}{R}}, \text{ for iron;}$ $\text{H.P.} = \frac{d^3 R}{55}; d = \sqrt[3]{\frac{55 \text{ H.P.}}{R}}, \text{ for cold-rolled iron.}$
For transmission simply, no pulleys:	{	$\text{H.P.} = \frac{d^3 R}{62.5}; d = \sqrt[3]{\frac{62.5 \text{ H.P.}}{R}}, \text{ for iron;}$ $\text{H.P.} = \frac{d^3 R}{35}; d = \sqrt[3]{\frac{35 \text{ H.P.}}{R}}, \text{ for cold-rolled iron.}$

H.P. = horse-power transmitted,  $d$  = diameter of shaft in inches,  $R$  = revolutions per minute.

J. B. Francis gives for turned-iron shafting  $d = \sqrt[3]{\frac{100 \text{ H.P.}}{R}}$ .

Jones and Laughlins give the same formulæ as Prof. Thurston, with the following exceptions: For line shafting, hangers 8 ft. apart:

$$\text{cold-rolled iron, H.P.} = \frac{d^3 R}{50}, d = \sqrt[3]{\frac{50 \text{ H.P.}}{R}}.$$

For simply transmitting power and short counters:

$$\text{turned iron, H.P.} = \frac{d^3 R}{50}, d = \sqrt[3]{\frac{50 \text{ H.P.}}{R}};$$

$$\text{cold-rolled iron, H.P.} = \frac{d^3 R}{30}, d = \sqrt[3]{\frac{30 \text{ H.P.}}{R}}.$$

They also give the following notes: Receiving and transmitting pulleys should always be placed as close to bearings as possible; and it is good practice to frame short "headers" between the main tie-beams of a mill so as to support the *main receivers*, carried by the head shafts, with a bearing close to each side as is contemplated in the formulæ. But if it is preferred, or necessary, for the shaft to span the full width of the "bay" without in-

intermediate bearings, or for the pulley to be placed away from the bearings towards or at the middle of the bay, the size of the shaft must be largely increased to secure the *stiffness* necessary to support the load without undue deflection. Shafts may not deflect more than 1/80 of an inch to each foot of clear length with safety.

To find the diameter of shaft necessary to carry safely the main pulley at the centre of a bay: Multiply the fourth power of the diameter obtained by above formulæ by the length of the "bay," and divide this product by the distance from centre to centre of the bearings when the shaft is supported as required by the formula. The fourth root of this quotient will be the diameter required.

The following table, computed by this rule, is practically correct and safe.

Diameter of Shaft given by the Formulæ for Head Shafts.	Diameter of Shaft necessary to carry the Load at the Centre of a Bay, which is from Centre to Centre of Bearings							
	2½ ft.	3 ft.	3½ ft.	4 ft.	5 ft.	6 ft.	8 ft.	10 ft.
in.	in.	in.	in.	in.	in.	in.	in.	in.
2	2⅛	2¼	2⅜	2½	2⅝	2¾	2⅞	3
2½	2½	2⅝	2¾	2⅞	3	3⅛	3⅜	3⅝
3	3	3⅛	3¼	3⅜	3½	3¾	4	4¼
3½	.....	3½	3⅝	3¾	4	4¼	4½	4¾
4	.....	4	4⅛	4¼	4½	4¾	5⅛	5⅜
4½	.....	.....	4½	4⅝	4⅞	5⅛	5½	5⅞
5	.....	.....	5	5⅛	5⅜	5⅝	6	6¼
5½	.....	.....	.....	5½	5¾	6	6½	6⅞
6	.....	.....	.....	6	6⅜	6⅝	7⅛	7¼

As the strain upon a shaft from a load upon it is proportional to the product of the parts of the shaft multiplied into each other, therefore, should the load be applied near one end of the span or bay instead of at the centre, multiply the fourth power of the diameter of the shaft required to carry the load at the centre of the span or bay by the product of the two parts of the shaft when the load is near one end, and divide this product by the product of the two parts of the shaft when the load is carried at the centre. The fourth root of this quotient will be the diameter required.

The shaft in a line which carries a receiving-pulley, or which carries a transmitting-pulley to drive another line, should always be considered a head-shaft, and should be of the size given by the rules for shafts carrying main pulleys or gears.

**Deflection of Shafting.** (Pencoyd Iron Works.)—As the deflection of steel and iron is practically alike under similar conditions of dimensions and loads, and as shafting is usually determined by its transverse stiffness rather than its ultimate strength, nearly the same dimensions should be used for steel as for iron.

For continuous line-shafting it is considered good practice to limit the deflection to a maximum of 1/100 of an inch per foot of length. The weight of bare shafting in pounds =  $2.6d^2L = W$ , or when as fully loaded with pulleys as is customary in practice, and allowing 40 lbs. per inch of width for the vertical pull of the belts, experience shows the load in pounds to be about  $13d^2L = W$ . Taking the modulus of transverse elasticity at 26,000,000 lbs., we derive from authoritative formulæ the following:

$$L = \sqrt[3]{873d^2}, \quad d = \sqrt{\frac{L^3}{873}}, \text{ for bare shafting;}$$

$$L = \sqrt[3]{175d^2}, \quad d = \sqrt{\frac{L^3}{175}}, \text{ for shafting carrying pulleys, etc. ;}$$

*L* being the maximum distance in feet between bearings for continuous shafting subjected to bending stress alone, *d* = diam. in inches.

The torsional stress is inversely proportional to the velocity of rotation, while the bending stress will not be reduced in the same ratio. It is therefore impossible to write a formula covering the whole problem and suffi-

ciently simple for practical application, but the following rules are correct within the range of velocities usual in practice.

For continuous shafting so proportioned as to deflect not more than 1/100 of an inch per foot of length, allowance being made for the weakening effect of key-seats,

$$d = \sqrt[3]{\frac{50 \text{ H.P.}}{R}}, L = \sqrt[3]{720d^2}, \text{ for bare shafts;}$$

$$d = \sqrt[3]{\frac{70 \text{ H.P.}}{R}}, L = \sqrt[3]{140d^2}, \text{ for shafts carrying pulleys, etc.}$$

$d$  = diam. in inches,  $L$  = length in feet,  $R$  = revs. per min.

The following table (by J. B. Francis) gives the greatest admissible distances between the bearings of continuous shafts subject to no transverse strain except from their own weight, as would be the case were the power given off from the shaft equal on all sides, and at an equal distance from the hanger-bearings.

Diam. of Shaft, in inches.	Distance between Bearings, in ft.		Diam. of Shaft, in inches.	Distance between Bearings, in ft.	
	Wrought-iron Shafts.	Steel Shafts.		Wrought-iron Shafts.	Steel Shafts.
2	15.46	15.89	6	22.30	22.92
3	17.70	18.19	7	23.48	24.13
4	19.48	20.02	8	24.55	25.23
5	20.99	21.57	9	25.53	26.24

These conditions, however, do not usually obtain in the transmission of power by belts and pulleys, and the varying circumstances of each case render it impracticable to give any rule which would be of value for universal application.

For example, the theoretical requirements would demand that the bearings be nearer together on those sections of shafting where most power is delivered from the shaft, while considerations as to the location and desired contiguity of the driven machines may render it impracticable to separate the driving-pulleys by the intervention of a hanger at the theoretically required location. (Joshua Rose.)

SPEED OF SHAFTING.—Machine shops ..... 120 to 180  
 Wood-working ..... 250 to 300  
 Cotton and woollen mills ..... 300 to 400

There are in some factories lines 1000 ft. long, the power being applied at the middle.

**Hollow Shafts.**—Let  $d$  be the diameter of a solid shaft, and  $d_1d_2$  the external and internal diameters of a hollow shaft of the same material. Then the shafts will be of equal torsional strength when  $d^3 = \frac{d_1^4 - d_2^4}{d_1}$ . A 10-inch hollow shaft with internal diameter of 4 inches will weigh 16% less than a solid 10-inch shaft, but its strength will be only 2.56% less. If the hole were increased to 5 inches diameter the weight would be 25% less than that of the solid shaft, and the strength 6.25% less.

**Table for Laying Out Shafting.**—The table on the opposite page (from the *Stevens Indicator*, April, 1892) is used by Wm. Sellers & Co. to facilitate the laying out of shafting.

The wood-cuts at the head of this table show the position of the hangers and position of couplings, either for the case of extension in both directions from a central head-shaft or extension in one direction from that head-shaft.

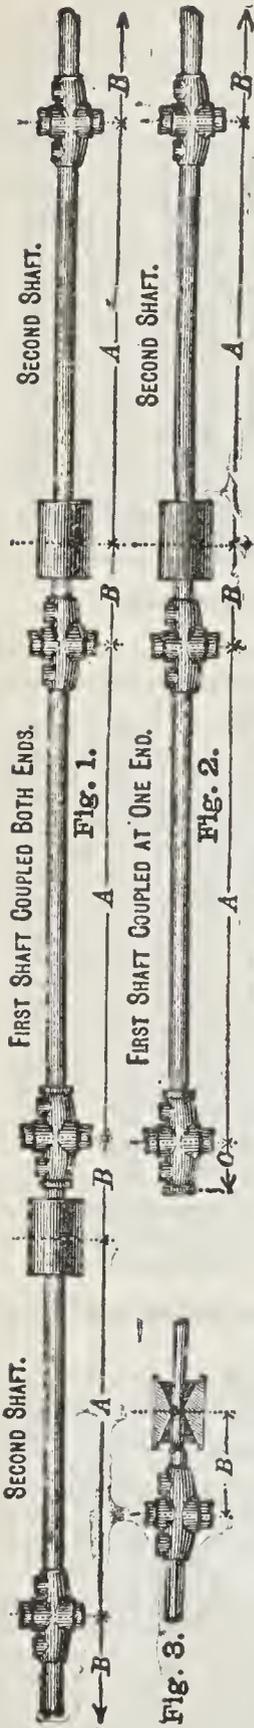

Table for Laying Out Shafting.

Length of Collared End for Fast Coll., ins.	Nominal Size of 2d Shaft.	Distance from Centre of Bearing to End of Shaft for Coupling. See B, Figs. 1, 2, and 3. PULLEYS.

**Proportions of Pulleys.** (See also Fly-wheels, pages 820 to 823).— Let  $n$  = number of arms,  $D$  = diameter of pulley,  $S$  = thickness of belt,  $t$  = thickness of rim at edge,  $T$  = thickness in middle,  $B$  = width of rim,  $\beta$  = width of belt,  $h$  = breadth of arm at hub,  $h_1$  = breadth of arm at rim,  $e$  = thickness of arm at hub  $e_1$  = thickness of arm at rim,  $c$  = amount of crowning; dimensions in inches.

		Unwin.	Reuleaux.
$B$ = width of rim.....		$9/8 (\beta + 0.4)$	$9/8\beta$ to $5/4\beta$
$t$ = thickness at edge of rim.....		$0.7S + .005D$	} (thick. of rim.) $1/5h$ to $1/4h$ .....
$T$ = " " middle of rim.....		$2t + c$	
$h$ = breadth of arm at hub.....	} For single belts = $.6337 \sqrt[3]{\frac{BD}{n}}$	$\sqrt[3]{\frac{BD}{n}}$	$\frac{1/4''}{4} + \frac{B}{4} + \frac{D}{20n}$
$h_1$ = " " " " rim.....		$2/3h$	$0.8h$
$e$ = thickness of arm at hub.....		$0.4h$	$0.5h$
$e_1$ = " " " " rim.....		$0.4h_1$	$0.5h_1$
$n$ = number of arms, for a } single set, }		$3 + \frac{BD}{150}$	$1/2 \left( 5 \times \frac{D}{2B} \right)$
$L$ = length of hub .....	} not less than $2.5S$ , is often $2/3B$ .		$B$ for sin.-arm pulleys. $2B$ " double-arm "
$M$ = thickness of metal in hub.....		.....	$h$ to $3/4h$
$c$ = crowning of pulley.....		$1/24B$	.....

The number of arms is really arbitrary, and may be altered if necessary. (Unwin.)

Pulleys with two or three sets of arms may be considered as two or three separate pulleys combined in one, except that the proportions of the arms should be 0.8 or 0.7 time that of single-arm pulleys. (Reuleaux.)

EXAMPLE.—Dimensions of a pulley 60'' diam., 16'' face, for double belt 1/2'' thick.

Solution by....	$n$	$h$	$h_1$	$e$	$e_1$	$t$	$T$	$L$	$M$	$c$
Unwin.....	9	3.79	2.53	1.52	1.01	.65	1.97	10.7	3.8	.67
Reuleaux... ..	4	5.0	4.0	2.5	2.0	1.25		16	5	

The following proportions are given in an article in the *Amer. Machinist*, authority not stated:

$h = .0625D + .5$  in.,  $h_1 = .04D + 3125$  in.,  $e = .025D + .2$  in.,  $e_1 = .016D + .125$  in.

These give for the above example:  $h = 4.25$  in.,  $h_1 = 2.71$  in.,  $e = 1.7$  in.  $e_1 = 1.09$  in. The section of the arms in all cases is taken as elliptical.

The following solution for breadth of arm is proposed by the author: Assume a belt pull of 45 lbs. per inch of width of a single belt, that the whole strain is taken in equal proportions on one half of the arms, and that the arm is a beam loaded at one end and fixed at the other. We have the

formula for a beam of elliptical section  $fP = .0982 \frac{Rbd^2}{l}$ , in which  $P$  = the load,  $R$  = the modulus of rupture of the cast iron,  $b$  = breadth,  $d$  = depth, and  $l$  = length of the beam, and  $f$  = factor of safety. Assume a modulus of rupture of 36,000 lbs., a factor of safety of 10, and an additional allowance for safety in taking  $l = 1/2$  the diameter of the pulley instead of  $1/2D$  less the radius of the hub.

Take  $d = h$ , the breadth of the arm at the hub, and  $b = e = 0.4h$ , the thickness. We then have  $fP = 10 \times \frac{45B}{n \div 2} = 900 \frac{B}{n} = \frac{3535 \times 0.4h^3}{1/2D}$ , whence

$h = \sqrt[3]{\frac{900BD}{3535n}} = .633 \sqrt[3]{\frac{BD}{n}}$ , which is practically the same as the value

reached by Unwin from a different set of assumptions.

**Convexity of Pulleys.**—Authorities differ. Morin gives a rise equal to 1/10 of the face; Molesworth, 1/24; others from 1/8 to 1/96. Scott A. Smith says the crown should not be over 1/8 inch for a 24-inch face. Pulleys for shifting belts should be "straight," that is, without crowning.

### CONE OR STEP PULLEYS.

To find the diameters for the several steps of a pair of cone-pulleys:

1. **Crossed Belts.**—Let  $D$  and  $d$  be the diameters of two pulleys connected by a crossed belt,  $L$  = the distance between their centres, and  $\beta$  = the angle either half of the belt makes with a line joining the centres of the pulleys: then total length of belt =  $(D + d)\frac{\pi}{2} + (D + d)\frac{\pi\beta}{180} + 2L \cos \beta$ .

$\beta$  = angle whose sine is  $\frac{D + d}{2L}$ ;  $L \cos \beta = \sqrt{L^2 - \left(\frac{D + d}{2}\right)^2}$ . The length of

the belt is constant when  $D + d$  is constant; that is, in a pair of step-pulleys the belt tension will be uniform when the sum of the diameters of each opposite pair of steps is constant. Crossed belts are seldom used for cone-pulleys, on account of the friction between the rubbing parts of the belt.

To design a pair of tapering speed-cones, so that the belt may fit equally tight in all positions: When the belt is crossed, use a pair of equal and similar cones tapering opposite ways.

2. **Open Belts.**—When the belt is uncrossed, use a pair of equal and similar conoids tapering opposite ways, and bulging in the middle, according to the following formula: Let  $L$  denote the distance between the axes of the conoids;  $R$  the radius of the larger end of each;  $r$  the radius of the smaller end; then the radius in the middle,  $r_0$ , is found as follows:

$$r_0 = \frac{R + r}{2} + \frac{(R - r)^2}{6.28L}. \quad (\text{Rankine.})$$

If  $D_0$  = the diameter of equal steps of a pair of cone-pulleys,  $D$  and  $d$  = the diameters of unequal opposite steps, and  $L$  = distance between the axes,  $D_0 = \frac{D + d}{2} + \frac{(D - d)^2}{12.566L}$ .

If a series of differences of radii of the steps,  $R - r$ , be assumed, then for each pair of steps  $\frac{R + r}{2} = r_0 - \frac{(R - r)^2}{6.28L}$ , and the radii of each may be computed from their half sum and half difference, as follows:

$$R = \frac{R + r}{2} + \frac{R - r}{2}; \quad r = \frac{R + r}{2} - \frac{R - r}{2}.$$

A. J. Frith (Trans. A. S. M. E., x. 298) shows the following application of Rankine's method: If we had a set of cones to design, the extreme diameters of which, including thickness of belt, were 40'' and 10'', and the ratio desired 4, 3, 2, and 1, we would make a table as follows,  $L$  being 100'':

Trial Sum of $D + d$ .	Ratio.	Trial Diameters.		Values of $(D - d)^2$ 12.56L	Amount to be Added.	Corrected Values.	
		$D$	$d$			$D$	$d$
50	4	40	10	.7165	.0000	40	10
50	3	37.5	12.5	.4975	.2190	37.7190	12.7190
50	2	33.333	16.666	.2212	.4953	33.8286	17.1619
50	1	25	25	.0000	.7165	25.7165	25.7165

The above formulæ are approximate, and they do not give satisfactory results when the difference of diameters of opposite steps is large and when the axes of the pulleys are near together, giving a large belt-angle. The following more accurate solution of the problem is given by C. A. Smith (Trans. A. S. M. E., x. 269) (Fig 152):

Lay off the centre distance  $C$  or  $EF$ , and draw the circles  $D_1$  and  $d_1$  equal to the first pair of pulleys, which are always previously determined by known conditions. Draw  $HI$  tangent to the circles  $D_1$  and  $d_1$ . From  $B$ , midway between  $E$  and  $F$ , erect the perpendicular  $BG$ , making the length

$BG = .314C$ . With  $G$  as a centre, draw a circle tangent to  $HI$ . Generally this circle will be outside of the belt-line, as in the cut, but when  $C$  is short and the first pulleys  $D_1$  and  $d_1$  are large, it will fall on the inside of the belt-line. The belt-line of any other pair of pulleys must be tangent to the circle  $G$ ; hence any line, as  $JK$  or  $LM$ , drawn tangent to the circle  $G$ , will give

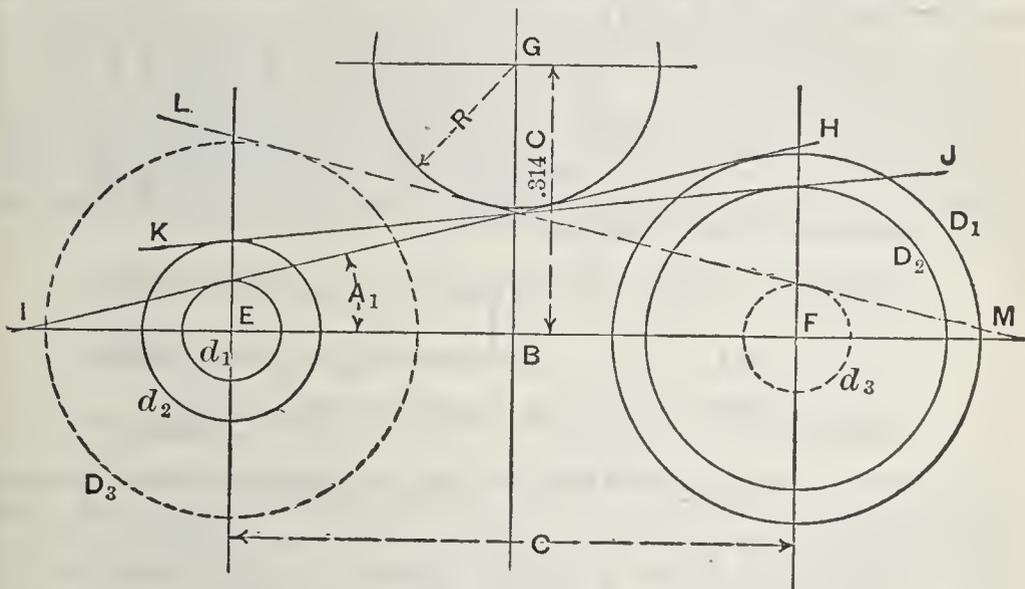

FIG. 152.

the diameters  $D_2, d_2$  or  $D_3, d_3$  of the pulleys drawn tangent to these lines from the centres  $E$  and  $F$ .

The above method is to be used when the belt-angle  $A$  does not exceed  $18^\circ$ . When it is between  $18^\circ$  and  $30^\circ$  a slight modification is made. In that case, in addition to the point  $G$ , locate another point  $m$  on the line  $BG$  .298  $C$  above  $B$ . Draw a tangent line to the circle  $G$ , making an angle of  $18^\circ$  to the line of centres  $EF$ , and from the point  $m$  draw an arc tangent to this tangent line. All belt-lines with angles greater than  $13^\circ$  are tangent to this arc. The following is the summary of Mr. Smith's mathematical method:

- $A$  = angle in degrees between the centre line and the belt of any pair of pulleys;
- $a = .314$  for belt-angles less than  $18^\circ$ , and  $.298$  for angles between  $18^\circ$  and  $30^\circ$ ;
- $B^\circ$  = an angle depending on the velocity ratio;
- $C$  = the centre distance of the two pulleys;
- $D, d$  = diameters of the larger and smaller of the pair of pulleys;
- $E^\circ$  = an angle depending on  $B^\circ$ ;
- $L$  = the length of the belt when drawn tight around the pulleys;
- $r = D \div d$ , or the velocity ratio (larger divided by smaller).

$$(1) \sin A = \frac{D - d}{2C}; \quad (2) \tan B^\circ = \frac{2a(r - 1)}{r + 1};$$

$$(3) \sin E^\circ = \sin B^\circ \left( \cos A - \frac{D + d}{4aC} \right);$$

$$(4) A = B^\circ - E^\circ \text{ when } \sin E^\circ \text{ is positive; } = B^\circ + E^\circ \text{ when } \sin E^\circ \text{ is negative;}$$

$$(5) d = \frac{2C \sin A}{r - 1}; = .3183(L - 2C) \text{ when } A = 0 \text{ and } r = 1;$$

$$(6) D = rd;$$

$$(7) L = 2C \cos A + .01745d[180 + (r - 1)(90 + A)].$$

Equation (1) is used only once for any pair of cones to obtain the constant  $\cos A$ , by the aid of tables of sines and cosines, for use in equation (3).

BELTING.

**Theory of Belts and Bands.**—A pulley is driven by a belt by means of the friction between the surfaces in contact. Let  $T_1$  be the tension on the driving side of the belt,  $T_2$  the tension on the loose side; then  $S = T_1 - T_2$ , is the total friction between the band and the pulley, which is equal to the tractive or driving force. Let  $f$  = the coefficient of friction,  $\theta$  the ratio of the length of the arc of contact to the length of the radius,  $a$  = the angle of the arc of contact in degrees,  $e$  = the base of the Napierian logarithms = 2.71828,  $m$  = the modulus of the common logarithms = 0.434295. The following formulæ are derived by calculus (Rankine's Mach'y & Millwork, p. 351; Carpenter's Exper. Eng'g, p. 173):

$$\frac{T_1}{T_2} = e^{f\theta}; \quad T_2 = \frac{T_1}{e^{f\theta}}; \quad T_1 - T_2 = T_1 - \frac{T_1}{e^{f\theta}} = T_1(1 - e^{-f\theta}).$$

$$T_1 - T_2 = T_1(1 - e^{-f\theta}) = T_1(1 - 10^{-f\theta m}) = T_1(1 - 10^{-.00758fa});$$

$$\frac{T_1}{T_2} = 10^{.00758fa}; \quad T_1 = T_2 \times 10^{.00758fa}; \quad T_2 = \frac{T_1}{10^{.00758fa}}.$$

If the arc of contact between the band and the pulley expressed in turns and fractions of a turn =  $n$ ,  $\theta = 2\pi n$ ;  $e^{f\theta} = 10^{2.7288fn}$ ; that is,  $e^{f\theta}$  is the natural number corresponding to the common logarithm  $2.7288fn$ .

The value of the coefficient of friction  $f$  depends on the state and material of the rubbing surfaces. For leather belts on iron pulleys, Morin found  $f = .56$  when dry,  $.36$  when wet,  $.23$  when greasy, and  $.15$  when oily. In calculating the proper mean tension for a belt, the smallest value,  $f = .15$ , is to be taken if there is a probability of the belt becoming wet with oil. The experiments of Henry R. Towne and Robert Briggs, however (Jour. Frank. Inst., 1868), show that such a state of lubrication is not of ordinary occurrence; and that in designing machinery we may in most cases safely take  $f = 0.42$ . Reuleaux takes  $f = 0.25$ . The following table shows the values of the coefficient  $2.7288f$ , by which  $n$  is multiplied in the last equation, corresponding to different values of  $f$ ; also the corresponding values of various ratios among the forces, when the arc of contact is half a circumference :

$f = 0.15$	0.25	0.42	0.56
$2.7288f = 0.41$	0.68	1.15	1.53

Let  $\theta = \pi$  and  $n = \frac{1}{2}$ , then

$T_1 \div T_2 = 1.603$	2.188	3.758	5.821
$T_1 \div S = 2.66$	1.84	1.36	1.21
$T_1 + T_2 \div 2S = 2.16$	1.34	0.86	0.71

In ordinary practice it is usual to assume  $T_2 = S$ ;  $T_1 = 2S$ ;  $T_1 + T_2 \div 2S = 1.5$ . This corresponds to  $f = 0.22$  nearly.

For a wire rope on cast iron  $f$  may be taken as 0.15 nearly; and if the groove of the pulley is bottomed with gutta-percha, 0.25. (Rankine.)

**Centrifugal Tension of Belts.**—When a belt or band runs at a high velocity, centrifugal force produces a tension in addition to that existing when the belt is at rest or moving at a low velocity. This centrifugal tension diminishes the effective driving force.

Rankine says: If an endless band, of any figure whatsoever, runs at a given speed, the centrifugal force produces a uniform tension at each cross-section of the band, equal to the weight of a piece of the band whose length is twice the height from which a heavy body must fall, in order to acquire the velocity of the band. (See Cooper on Belting, p. 101.)

If  $T_c$  = centrifugal tension;

$V$  = velocity in feet per second;

$g$  = acceleration due to gravity = 32.2;

$W$  = weight of a piece of the belt 1 ft. long and 1 sq. in. sectional area,—

Leather weighing 56 lbs. per cubic foot gives  $W = 56 \div 144 = .388$ .

$$T_c = \frac{WV^2}{g} = \frac{.388V^2}{32.2} = .012V^2.$$

**Belting Practice. Handy Formulæ for Belting.** — Since in the practical application of the above formulæ the value of the coefficient of friction must be assumed, its actual value varying within wide limits (15% to 135%), and since the values of  $T_1$  and  $T_2$  also are fixed arbitrarily, it is customary in practice to substitute for these theoretical formulæ more simple empirical formulæ and rules, some of which are given below.

Let  $d$  = diam. of pulley in inches;  $\pi d$  = circumference;  
 $V$  = velocity of belt in ft. per second;  $v$  = vel. in ft. per minute;  
 $a$  = angle of the arc of contact;  
 $L$  = length of arc of contact in feet =  $\pi da + (12 \times 360)$ ;  
 $F$  = tractive force per square inch of sectional area of belt;  
 $w$  = width in inches;  $t$  = thickness;  
 $S$  = tractive force per inch of width =  $F \div t$ ;  
 rpm. = revs. per minute; rps. = revs. per second = rpm.  $\div$  60.

$$V = \frac{\pi d}{12} \times \text{rps.} = \frac{\pi d}{12} \times \frac{\text{rpm.}}{60} = .004363d \times \text{rpm.} = \frac{d \times \text{rpm.}}{229.2};$$

$$v = \frac{\pi d}{12} \times \text{rpm.}; = .2618d \times \text{rpm.}$$

$$\text{Horse-power, H.P.} = \frac{Svw}{33000} = \frac{SVw}{550} = \frac{Sw d \times \text{rpm.}}{126050} = .00007933Sw d \times \text{rpm.}$$

If  $F$  = working tension per square inch = 275 lbs., and  $t = 7/32$  inch,  $S = 60$  lbs. nearly, then

$$\text{H.P.} = \frac{vw}{550} = .109Vw = .000476wd \times \text{rpm.} = \frac{wd \times \text{rpm.}}{2101}. \quad (1)$$

If  $F = 180$  lbs. per square inch, and  $t = 1/6$  inch,  $S = 30$  lbs., then

$$\text{H.P.} = \frac{vw}{1100} = .055Vw = .000238wd \times \text{rpm.} = \frac{wd \times \text{rpm.}}{4202}. \quad (2)$$

If the working strain is 60 lbs. per inch of width, a belt 1 inch wide travelling 550 ft. per minute will transmit 1 horse-power. If the working strain is 30 lbs. per inch of width, a belt 1 inch wide, travelling 1100 ft. per minute, will transmit 1 horse-power. Numerous rules are given by different writers on belting which vary between these extremes. A rule commonly used is: 1 inch wide travelling 1000 ft. per min. = 1 H.P.

$$\text{H.P.} = \frac{vw}{1000} = .06Vw = .000262wd \times \text{rpm.} = \frac{wd \times \text{rpm.}}{3820}. \quad (3)$$

This corresponds to a working strain of 33 lbs. per inch of width.

Many writers give as safe practice for single belts in good condition a working tension of 45 lbs. per inch of width. This gives

$$\text{H.P.} = \frac{vw}{733} = .0818Vw = .000357wd \times \text{rpm.} = \frac{wd \times \text{rpm.}}{2800}. \quad (4)$$

For double belts of average thickness, some writers say that the transmitting efficiency is to that of single belts as 10 to 7, which would give

$$\text{H.P. of double belts} = \frac{vw}{513} = .1169Vw = .00051wd \times \text{rpm.} = \frac{wd \times \text{rpm.}}{1960}. \quad (5)$$

Other authorities, however, make the transmitting-power of double belts twice that of single belts, on the assumption that the thickness of a double-belt is twice that of a single belt.

Rules for horse-power of belts are sometimes based on the number of square feet of surface of the belt which pass over the pulley in a minute. Sq. ft. per min. =  $wv \div 12$ . The above formulæ translated into this form give:

- |     |                                  |                               |
|-----|----------------------------------|-------------------------------|
| (1) | For $S = 60$ lbs. per inch wide; | H.P. = 46 sq. ft. per minute. |
| (2) | “ $S = 30$ “ “ “                 | H.P. = 92 “ “                 |
| (3) | “ $S = 33$ “ “ “                 | H.P. = 83 “ “                 |
| (4) | “ $S = 45$ “ “ “                 | H.P. = 61 “ “                 |
| (5) | “ $S = 64.3$ “ “ “               | H.P. = 43 “ “ (double belt).  |

The above formulæ are all based on the supposition that the arc of contact is 180°. For other arcs, the transmitting power is approximately proportional to the ratio of the degrees of arc to 180°.

Some rules base the horse-power on the length of the arc of contact in feet. Since  $L = \frac{\pi da}{12 \times 360}$  and  $H.P. = \frac{Srvw}{33000} = \frac{Sw}{33000} \times \frac{\pi d}{12} \times \text{rpm.} \times \frac{a}{180}$ , we obtain by substitution  $H.P. = \frac{Sw}{16500} \times L \times \text{rpm.}$ , and the five formulæ then take the following form for the several values of  $S$ :

$$H.P. = \frac{wL \times \text{rpm.}}{275} \quad (1); \quad \frac{wL \times \text{rpm.}}{550} \quad (2); \quad \frac{wL \times \text{rpm.}}{500} \quad (3); \quad \frac{wL \times \text{rpm.}}{367} \quad (4);$$

$$H.P. \text{ (double belt)} = \frac{wL \times \text{rpm.}}{257} \quad (5).$$

None of the handy formulæ take into consideration the centrifugal tension of belts at high velocities. When the velocity is over 3000 ft. per minute the effect of this tension becomes appreciable, and it should be taken account of as in Mr. Nagle's formula, which is given below.

**Horse-power of a Leather Belt One Inch wide. (NAGLE.)**

$$\text{Formula: } H.P. = CVtw(S - .012V^2) \div 550.$$

$$\text{For } f = .40, a = 180^\circ, C = .715, w = 1.$$

**Width of Belt for a Given Horse-power.**—The width of belt required for any given horse-power may be obtained by transposing the formulæ for horse-power so as to give the value of  $w$ . Thus:

$$\text{From formula (1), } w = \frac{550 \text{ H.P.}}{v} = \frac{9.17 \text{ H.P.}}{V} = \frac{2101 \text{ H.P.}}{d \times \text{rpm.}} = \frac{275 \text{ H.P.}}{L \times \text{rpm.}}$$

$$\text{From formula (2), } w = \frac{1100 \text{ H.P.}}{v} = \frac{18.33 \text{ H.P.}}{V} = \frac{4202 \text{ H.P.}}{d \times \text{rpm.}} = \frac{530 \text{ H.P.}}{L \times \text{rpm.}}$$

$$\text{From formula (3), } w = \frac{1000 \text{ H.P.}}{v} = \frac{16.67 \text{ H.P.}}{V} = \frac{3820 \text{ H.P.}}{d \times \text{rpm.}} = \frac{500 \text{ H.P.}}{L \times \text{rpm.}}$$

$$\text{From formula (4), } w = \frac{733 \text{ H.P.}}{v} = \frac{12.22 \text{ H.P.}}{V} = \frac{2800 \text{ H.P.}}{d \times \text{rpm.}} = \frac{360 \text{ H.P.}}{L \times \text{rpm.}}$$

$$\text{From formula (5),* } w = \frac{513 \text{ H.P.}}{v} = \frac{8.56 \text{ H.P.}}{V} = \frac{1960 \text{ H.P.}}{d \times \text{rpm.}} = \frac{257 \text{ H.P.}}{L \times \text{rpm.}}$$

\* For double belts.

Many authorities use formula (1) for double belts and formula (2) or (3) for single belts.

To obtain the width by Nagle's formula,  $w = \frac{550 \text{ H.P.}}{CVt(S - .012V^2)}$ , or divide the given horse-power by the figure in the table corresponding to the given thickness of belt and velocity in feet per second.

The formula to be used in any particular case is largely a matter of judgment. A single belt proportioned according to formula (1), if tightly stretched, and if the surface is in good condition, will transmit the horse-power calculated by the formula, but one so proportioned is objectionable, first, because it requires so great an initial tension that it is apt to stretch, slip, and require frequent restretching and relacing; and second, because this tension will cause an undue pressure on the pulley-shaft, and therefore an undue loss of power by friction. To avoid these difficulties, formula (2), (3), or (4), or Mr. Nagle's table, should be used; the latter especially in cases in which the velocity exceeds 4000 ft. per min.

**Taylor's Rules for Belting.**—F. W. Taylor (Trans. A. S. M. E., xv. 204) describes a nine years' experiment on belting in a machine-shop, giving results of tests of 42 belts running night and day. Some of these belts were run on cone pulleys and others on shifting, or fast-and-loose, pulleys. The average net working load on the shifting belts was only 4/10 of that of the cone belts.

The shifting belts varied in dimensions from 39 ft. 7 in. long, 3.5 in. wide, .25 in. thick, to 51 ft. 5 in. long, 6.5 in. wide, .37 in. thick. The cone belts varied in dimensions from 24 ft. 7 in. long, 2 in. wide, .25 in. thick, to 31 ft. 10 in. long, 4 in. wide, .37 in. thick.

Belt-clamps were used having spring-balances between the two pairs of clamps, so that the exact tension to which the belt was subjected was accurately weighed when the belt was first put on, and each time it was tightened.

The tension under which each belt was spliced was carefully figured so as to place it under an initial strain—while the belt was at rest immediately after tightening—of 71 lbs. per inch of width of double belts. This is equivalent, in the case of

- Oak tanned and fulled belts, to 192 lbs. per sq. in. section;
- Oak tanned, not fulled belts, to 229 " " " " "
- Semi-raw-hide belts, to 253 " " " " "
- Raw-hide belts, to 284 " " " " "

From the nine years' experiment Mr. Taylor draws a number of conclusions, some of which are given in an abridged form below.

In using belting so as to obtain the greatest economy and the most satisfactory results, the following rules should be observed:

	Oak Tanned and Fulled Leather Belts.	Other Types of Leather Belts and 6- to 7-ply Rubber Belts.
A double belt, having an arc of contact of 180°, will give an effective pull on the face of a pulley per inch of width of belt of....	35 lbs.	30 lbs.
Or, a different form of same rule: The number of sq. ft. of double Belt passing around a pulley per minute required to transmit one horse-power is.....	80 sq. ft.	90 sq. ft.
Or: The number of lineal feet of double-belting 1 in. wide passing around a pulley per minute required to transmit one horse-power is.....	950 ft.	1100 ft.
Or: A double belt 6 in. wide, running 4000 to 5000 ft. per min., will transmit.....	30 H.P.	25 H.P.

The terms "initial tension," "effective pull," etc., are thus explained by Mr. Taylor: When pulleys upon which belts are tightened are at rest, both strands of the belt (the upper and lower) are under the same stress per in. of width. By "tension," "initial tension," or "tension while at rest," we

mean the stress per in. of width, or sq. in. of section, to which one of the strands of the belt is tightened, when at rest. After the belts are in motion and transmitting power, the stress on the slack side, or strand, of the belt becomes less, while that on the tight side—or the side which does the pulling—becomes greater than when the belt was at rest. By the term "total load" we mean the total stress per in. of width, or sq. in. of section, on the tight side of belt while in motion.

The difference between the stress on the tight side of the belt and its slack side, while in motion, represents the effective force or pull which is transmitted from one pulley to another. By the terms "working load," "net working load," or "effective pull," we mean the difference in the tension of the tight and slack sides of the belt per in. of width, or sq. in. section, while in motion, or the net effective force that is transmitted from one pulley to another per in. of width or sq. in. of section.

The discovery of Messrs. Lewis and Bancroft (Trans. A. S. M. E., vii. 749) that the "sum of the tension on both sides of the belt does not remain constant," upsets all previous theoretical belting formulæ.

The belt speed for maximum economy should be from 4000 to 4500 ft. per minute.

The best distance from centre to centre of shafts is from 20 to 25 ft.

Idler pulleys work most satisfactorily when located on the slack side of the belt about one quarter way from the driving-pulley.

Belts are more durable and work more satisfactorily made narrow and thick, rather than wide and thin.

It is safe and advisable to use: a double belt on a pulley 12 in. diameter or larger; a triple belt on a pulley 20 in. diameter or larger; a quadruple belt on a pulley 30 in. diameter or larger.

As belts increase in width they should also be made thicker.

The ends of the belt should be fastened together by splicing and cementing, instead of lacing, wiring, or using hooks or clamps of any kind.

A V-splice should be used on triple and quadruple belts and when idlers are used. Stepped splice, coated with rubber and vulcanized in place, is best for rubber belts.

For double belting the rule works well of making the splice for all belts up to 10 in. wide, 10 in. long; from 10 in. to 18 in. wide the splice should be the same width as the belt, 18 in. being the greatest length of splice required for double belting.

Belts should be cleaned and greased every five to six months.

Double leather belts will last well when repeatedly tightened under a strain (when at rest) of 71 lbs. per in. of width, or 240 lbs. per sq. in. section. They will not maintain this tension for any length of time, however.

Belt-clamps having spring-balances between the two pairs of clamps should be used for weighing the tension of the belt accurately each time it is tightened.

The stretch, durability, cost of maintenance, etc., of belts proportioned (A) according to the ordinary rules of a total load of 111 lbs. per inch of width corresponding to an effective pull of 65 lbs. per inch of width, and (B) according to a more economical rule of a total load of 54 lbs., corresponding to an effective pull of 26 lbs. per inch of width, are found to be as follows:

When it is impracticable to accurately weigh the tension of a belt in tightening it, it is safe to shorten a double belt one half inch for every 10 ft. of length for (A) and one inch for every 10 ft. for (B), if it requires tightening.

Double leather belts, when treated with great care and run night and day at moderate speed, should last for 7 years (A); 18 years (B).

The cost of all labor and materials used in the maintenance and repairs of double belts, added to the cost of renewals as they give out, through a term of years, will amount on an average per year to 37% of the original cost of the belts (A); 14% or less (B).

In figuring the total expense of belting, and the manufacturing cost chargeable to this account, by far the largest item is the time lost on the machines while belts are being relaced and repaired.

The total stretch of leather belting exceeds 6% of the original length.

The stretch during the first six months of the life of belts is 36% of their entire stretch (A); 15% (B).

A double belt will stretch  $\frac{47}{100}$  of 1% of its length before requiring to be tightened (A);  $\frac{81}{100}$  of 1% (B).

The most important consideration in making up tables and rules for the use and care of belting is how to secure the minimum of interruptions to manufacture from this source.

The average double belt (A), when running night and day in a machine-shop, will cause at least 26 interruptions to manufacture during its life, or 5 interruptions per year, but with (B) interruptions to manufacture will not average oftener for each belt than one in sixteen months.

The oak-tanned and fulled belts showed themselves to be superior in all respects except the coefficient of friction to either the oak-tanned, not fulled, the semi-raw-hide, or raw-hide with tanned face.

Belts of any width can be successfully shifted backward and forward on tight and loose pulleys. Belts running between 5000 and 6000 ft. per min. and driving 300 H.P. are now being daily shifted on tight and loose pulleys, to throw lines of shafting in and out of use.

The best form of belt-shifter for wide belts is a pair of rollers twice the width of belt, either of which can be pressed onto the flat surface of the belt on its slack side close to the driven pulley, the axis of the roller making an angle of 75° with the centre line of the belt.

**Remarks on Mr. Taylor's Rules.** (Trans. A. S. M. E., xv., 242.) —The most notable feature in Mr. Taylor's paper is the great difference between his rules for proper proportioning of belts and those given by earlier writers. A very commonly used rule is, one horse-power may be transmitted by a single belt 1 in. wide running  $x$  ft. per min., substituting for  $x$  various values, according to the ideas of different engineers, ranging usually from 550 to 1100.

The practical mechanic of the old school is apt to swear by the figure 600 as being thoroughly reliable, while the modern engineer is more apt to use the figure 1000. Mr. Taylor, however, instead of using a figure from 550 to 1100 for a single belt, uses 950 to 1100 for double belts. If we assume that a double belt is twice as strong, or will carry twice as much power, as a single belt, then he uses a figure at least twice as large as that used in modern practice, and would make the cost of belting for a given shop twice as large as if the belting were proportioned according to the most liberal of the customary rules.

This great difference is to some extent explained by the fact that the problem which Mr. Taylor undertakes to solve is quite a different one from that which is solved by the ordinary rules with their variations. The problem of the latter generally is, "How wide a belt must be used, or how narrow a belt may be used, to transmit a given horse-power?" Mr. Taylor's problem is: "How wide a belt must be used so that a given horse-power may be transmitted with the minimum cost for belt repairs, the longest life to the belt, and the smallest loss and inconvenience from stopping the machine while the belt is being tightened or repaired?"

The difference between the old practical mechanic's rule of a 1-in.-wide single belt, 600 ft. per min., transmits one horse-power, and the rule commonly used by engineers, in which 1000 is substituted for 600, is due to the belief of the engineers, not that a horse-power could not be transmitted by the belt proportioned by the older rule, but that such a proportion involved undue strain from overtightening to prevent slipping, which strain entailed too much journal friction, necessitated frequent tightening, and decreased the length of the life of the belt.

Mr. Taylor's rule substituting 1100 ft. per min. and doubling the belt is a further step, and a long one, in the same direction. Whether it will be taken in any case by engineers will depend upon whether they appreciate the extent of the losses due to slippage of belts slackened by use under overstrain, and the loss of time in tightening and repairing belts, to such a degree as to induce them to allow the first cost of the belts to be doubled in order to avoid these losses.

It should be noted that Mr. Taylor's experiments were made on rather narrow belts, used for transmitting power from shafting to machinery, and his conclusions may not be applicable to heavy and wide belts, such as engine fly-wheel belts.

### MISCELLANEOUS NOTES ON BELTING.

Formulæ are useful for proportioning belts and pulleys, but they furnish no means of estimating how much power a particular belt may be transmitting at any given time, any more than the size of the engine is a measure of the load it is actually drawing, or the known strength of a horse is a measure of the load on the wagon. The only reliable means of determining the power actually transmitted is some form of dynamometer. (See Trans. A. S. M. E., vol. xii. p. 707.)

If we increase the thickness, the power transmitted ought to increase in proportion; and for double belts we should have half the width required for a single belt under the same conditions. With large pulleys and moderate velocities of belt it is probable that this holds good. With small pulleys, however, when a double belt is used, there is not such perfect contact between the pulley-face and the belt, due to the rigidity of the latter, and more work is necessary to bend the belt-fibres than when a thinner and more pliable belt is used. The centrifugal force tending to throw the belt from the pulley also increases with the thickness, and for these reasons the width of a double belt required to transmit a given horse-power when used with small pulleys is generally assumed not less than seven tenths the width of a single belt to transmit the same power. (Flather on "Dynamometers and Measurement of Power.")

F. W. Taylor, however, finds that great pliability is objectionable, and favors thick belts even for small pulleys. The power consumed in bending the belt around the pulley he considers inappreciable. According to Rankine's formula for centrifugal tension, this tension is proportional to the sectional area of the belt, and hence it does not increase with increase of thickness when the width is decreased in the same proportion, the sectional area remaining constant.

Scott A. Smith (Trans. A. S. M. E., x, 765) says: The best belts are made from all oak-tanned leather, and curried with the use of cod oil and tallow, all to be of superior quality. Such belts have continued in use thirty to forty years when used as simple driving-belts, driving a proper amount of power, and having had suitable care. The flesh side should not be run to the pulley-face, for the reason that the wear from contact with the pulley should come on the grain side, as that surface of the belt is much weaker in its tensile strength than the flesh side; also as the grain is hard it is more enduring for the wear of attrition; further, if the grain is actually worn off, then the belt may not suffer in its integrity from a ready tendency of the hard grain side to crack.

The most intimate contact of a belt with a pulley comes, first, in the smoothness of a pulley-face, including freedom from ridges and hollows left by turning-tools; second, in the smoothness of the surface and evenness in the texture or body of a belt; third, in having the crown of the driving and receiving pulleys exactly alike,—as nearly so as is practicable in a commercial sense; fourth, in having the crown of pulleys not over  $\frac{1}{8}$ " for a 24" face, that is to say, that the pulley is not to be over  $\frac{1}{4}$ " larger in diameter in its centre; fifth, in having the crown other than two planes meeting at the centre; sixth, the use of any material on or in a belt, in addition to those necessarily used in the currying process, to keep them pliable or increase their tractive quality, should wholly depend upon the exigencies arising in the use of belts; non-use is safer than over-use; seventh, with reference to the lacing of belts, it seems to be a good practice to cut the ends to a convex shape by using a former, so that there may be a nearly uniform stress on the lacing through the centre as compared with the edges. For a belt 10" wide, the centre of each end should recede  $\frac{1}{10}$ ".

**Lacing of Belts.**—In punching a belt for lacing, use an oval punch, the longer diameter of the punch being parallel with the sides of the belt. Punch two rows of holes in each end, placed zigzag. In a 3-in. belt there should be four holes in each end—two in each row. In a 6-inch belt, seven holes—four in the row nearest the end. A 10-inch belt should have nine holes. The edge of the holes should not come nearer than  $\frac{3}{4}$  of an inch from the sides, nor  $\frac{7}{8}$  of an inch from the ends of the belt. The second row should be at least  $1\frac{3}{4}$  inches from the end. On wide belts these distances should be even a little greater.

Begin to lace in the centre of the belt and take care to keep the ends exactly in line, and to lace both sides with equal tightness. The lacing should not be crossed on the side of the belt that runs next the pulley. In taking up belts, observe the same rules as putting on new ones.

**Setting a Belt on Quarter-twist.**—A belt must run squarely on to the pulley. To connect with a belt two horizontal shafts at right angles with each other, say an engine-shaft near the floor with a line attached to the ceiling, will require a quarter-turn. First, ascertain the central point on the face of each pulley at the extremity of the horizontal diameter where the belt will leave the pulley, and then set that point on the driven pulley plumb over the corresponding point on the driver. This will cause the belt to run squarely on to each pulley, and it will leave at an angle greater or less, according to the size of the pulleys and their distance from each other.

In quarter-twist belts, in order that the belt may remain on the pulleys, the central plane on each pulley must pass through the point of delivery of the other pulley. This arrangement does not admit of reversed motion.

**To find the Length of Belt required for two given Pulleys.**—When the length cannot be measured directly by a tape-line, the following approximate rule may be used: Add the diameter of the two pulleys together, divide the sum by 2, and multiply the quotient by  $3\frac{1}{4}$ , and add the product to twice the distance between the centres of the shafts. (See accurate formula below.)

**To find the Angle of the Arc of Contact of a Belt.**—Divide the difference between the radii of the two pulleys in inches by the distance between their centres, also in inches, and in a table of natural sines find the angle most nearly corresponding with the quotient. Multiply this angle by 2, and add the product to  $180^\circ$  for the angle of contact with the larger pulley, or subtract it from  $180^\circ$  for the smaller pulley.

Or, let  $R$  = radius of larger pulley,  $r$  = radius of smaller;

$L$  = distance between centres of the pulleys;

$a$  = angle whose sine is  $(R - r) \div L$ .

Arc of contact with smaller pulley =  $180^\circ - 2a$ ;

“ “ “ “ larger pulley =  $180^\circ + 2a$ .

**To find the Length of Belt in Contact with the Pulley.**—For the larger pulley, multiply the angle  $a$ , found as above, by .0349, to the product add 3.1416, and multiply the sum by the radius of the pulley. Or length of belt in contact with the pulley

$$= \text{radius} \times (\pi + .0349a) = \text{radius} \times \pi \left(1 + \frac{a}{90}\right).$$

For the smaller pulley, length = radius  $\times (\pi - .0349a) = \text{radius} \times \pi \left(1 - \frac{a}{90}\right)$ .

The above rules refer to **Open Belts**. The accurate formula for length of an open belt is,

$$\text{Length} = \pi R \left(1 + \frac{a}{90}\right) + \pi r \left(1 - \frac{a}{90}\right) + 2L \cos a$$

$$= R(\pi + .0349a) + r(\pi - .0349a) + 2L \cos a,$$

in which  $R$  = radius of larger pulley,  $r$  = radius of smaller pulley,

$L$  = distance between centres of pulleys, and  $a$  = angle whose sine is

$$(R - r) \div L; \cos a = \sqrt{L^2 - (R - r)^2} \div L.$$

**For Crossed Belts** the formula is

$$\text{Length of belt} = \pi R \left(1 + \frac{\beta}{90}\right) + \pi r \left(1 + \frac{\beta}{90}\right) + 2L \cos \beta,$$

$$= (R + r) \times (\pi + .0349\beta) + 2L \cos \beta,$$

in which  $\beta$  = angle whose sine is  $(R + r) \div L$ ;  $\cos \beta = \sqrt{L^2 - (R + r)^2} \div L$ .

**To find the Length of Belt when Closely Rolled.**—The sum of the diameter of the roll, and of the eye in inches,  $\times$  the number of turns made by the belt and by .1309, = length of the belt in feet

**To find the Approximate Weight of Belts**—Multiply the length of belt, in feet, by the width in inches, and divide the product by 13 for single, and 8 for double belt.

**Relations of the Size and Speeds of Driving and Driven Pulleys.**—The driving pulley is called the driver,  $D$ , and the driven pulley the driven,  $d$ . If the number of teeth in gears is used instead of diameter, in these calculations, number of teeth must be substituted wherever diameter occurs.  $R$  = revs. per min. of driver,  $r$  = revs. per min. of driven.

$$D = dr \div R;$$

)Diam. of driver = diam. of driven  $\times$  revs. of driven  $\div$  revs. of driver.

$$d = DR \div r;$$

Diam. of driven = diam. of driver  $\times$  revs. of driver  $\div$  revs. of driven.

$$R = dr \div D;$$

Revs. of driver = revs. of driven  $\times$  diam. of driven  $\div$  diam. of driver.

$$r = DR \div d;$$

Revs. of driven = revs. of driver  $\times$  diam. of driver  $\div$  diam. of driven.

**Evils of Tight Belts.** (Jones and Laughlins.)—Clamps with powerful screws are often used to put on belts with extreme tightness, and with most injurious strain upon the leather. They should be very judiciously used for horizontal belts, which should be allowed sufficient slackness to move with a loose undulating vibration on the returning side, as a test that they have no more strain imposed than is necessary simply to transmit the power.

On this subject a New England cotton-mill engineer of large experience, says: I believe that three quarters of the trouble experienced in broken pulleys, hot boxes, etc., can be traced to the fault of tight belts. The enormous and useless pressure thus put upon pulleys must in time break them, if they are made in any reasonable proportions, besides wearing out the whole outfit, and causing heating and consequent destruction of the bearings. Below are some figures showing the power it takes in average modern mills with first-class shafting, to drive the shafting alone :

Mill, No.	Whole Load, H.P.	Shafting Alone.		Mill, No.	Whole Load, H.P.	Shafting Alone.	
		Horse-power.	Per cent of whole.			Horse-power.	Per cent of whole.
1	199	51	25.6	5	759	172.6	22.7
2	472	111.5	23.6	6	235	84.8	36.1
3	486	134	27.5	7	670	262.9	39.2
4	677	190	28.1	8	677	182	26.8

These may be taken as a fair showing of the power that is required in many of our best mills to drive shafting. It is unreasonable to think that all that power is consumed by a legitimate amount of friction of bearings and belts. I know of no cause for such a loss of power but tight belts. These, when there are hundreds or thousands in a mill, easily multiply the friction on the bearings, and would account for the figures.

**Sag of Belts.**—In the location of shafts that are to be connected with each other by belts, care should be taken to secure a proper distance one from the other. This distance should be such as to allow of a gentle sag to the belt when in motion.

A general rule may be stated thus: Where narrow belts are to be run over small pulleys 15 feet is a good average, the belt having a sag of  $1\frac{1}{2}$  to 2 inches.

For larger belts, working on larger pulleys, a distance of 20 to 25 feet does well, with a sag of  $2\frac{1}{2}$  to 4 inches.

For main belts working on very large pulleys, the distance should be 25 to 30 feet, the belts working well with a sag of 4 to 5 inches.

If too great a distance is attempted, the belt will have an unsteady flapping motion, which will destroy both the belt and machinery.

**Arrangement of Belts and Pulleys.**—If possible to avoid it, connected shafts should never be placed one directly over the other, as in such case the belt must be kept very tight to do the work. For this purpose belts should be carefully selected of well-stretched leather.

It is desirable that the angle of the belt with the floor should not exceed  $45^\circ$ . It is also desirable to locate the shafting and machinery so that belts should run off from each shaft in opposite directions, as this arrangement will relieve the bearings from the friction that would result when the belts all pull one way on the shaft.

In arranging the belts leading from the main line of shafting to the counters, those pulling in an opposite direction should be placed as near each other as practicable, while those pulling in the same direction should be separated. This can often be accomplished by changing the relative positions of the pulleys on the counters. By this procedure much of the friction on the journals may be avoided.

If possible, machinery should be so placed that the direction of the belt motion shall be from the top of the driving to the top of the driven pulley, when the sag will increase the arc of contact.

The pulley should be a little wider than the belt required for the work.

The motion of driving should run with and not against the laps of the belts. Tightening or guide pulleys should be applied to the slack side of belts and near the smaller pulley.

Jones & Laughlins, in their Useful Information, say: The diameter of the pulleys should be as large as can be admitted, provided they will not produce a speed of more than 4750 feet of belt motion per minute.

They also say: It is better to gear a mill with small pulleys and run them at a high velocity, than with large pulleys and to run them slower. A mill thus geared costs less and has a much neater appearance than with large heavy pulleys.

M. Arthur Achard (Proc. Inst. M. E., Jan. 1881, p. 62) says: When the belt is wide a partial vacuum is formed between the belt and the pulley at a high velocity. The pressure is then greater than that computed from the tensions in the belt, and the resistance to slipping is greater. This has the advantage of permitting a greater power to be transmitted by a given belt, and of diminishing the strain on the shafting.

On the other hand, some writers claim that the belt entraps air between itself and the pulley, which tends to diminish the friction, and reduce the tractive force. On this theory some manufacturers perforate the belt with numerous holes to let the air escape.

**Care of Belts.**—Leather belts should be well protected against water, loose steam, and all other moisture, with which they should not come in contact. But where such conditions prevail fairly good results are obtained by using a special dressing prepared for the purpose of water-proofing leather, though a positive water-proofing material has not yet been discovered.

Belts made of coarse, loose-fibred leather will do better service in dry and warm places, but if damp or moist conditions exist then the very finest and firmest leather should be used. (Fayerweather & Ladew.)

Do not allow oil to drip upon the belts. It destroys the life of the leather. Leather belting cannot safely stand above 110° of heat.

**Strength of Belting.**—The ultimate tensile strength of belting does not generally enter as a factor in calculations of power transmission.

The strength of the solid leather in belts is from 2000 to 5000 lbs. per square inch; at the lacings, even if well put together, only about 1000 to 1500. If riveted, the joint should have half the strength of the solid belt. The working strain on the driving side is generally taken at not over one third of the strength of the lacing, or from one eighth to one sixteenth of the strength of the solid belt. Dr. Hartig found that the tension in practice varied from 30 to 532 lbs. per square inch, averaging 273 lbs.

**Adhesion Independent of Diameter.** (Schultz Belting Co.)—

1. The adhesion of the belt to the pulley is the same—the arc or number of degrees of contact, aggregate tension or weight being the same—without reference to width of belt or diameter of pulley.

2. A belt will slip just as readily on a pulley four feet in diameter as it will on a pulley two feet in diameter, provided the conditions of the faces of the pulleys, the arc of contact, the tension, and the number of feet the belt travels per minute are the same in both cases.

3. To obtain a greater amount of power from belts the pulleys may be covered with leather; this will allow the belts to run very slack and give 25% more durability.

**Endless Belts.**—If the belts are to be endless, they should be put on and drawn together by "belt clamps" made for the purpose. If the belt is made endless at the belt factory, it should never be run on to the pulleys, lest the irregular strain spring the belt. Lift out one shaft, place the belt on the pulleys, and force the shaft back into place.

**Belt Data.**—A fly-wheel at the Amoskeag Mfg. Co., Manchester, N. H., 30 feet diameter, 110 inches face, running 61 revs. per min., carried two heavy double-leather belts 40 inches wide each, and one 24 inches wide. The engine indicated 1950 H.P., of which probably 1850 H.P. was transmitted by the belts. The belts were considered to be heavily loaded, but not overtaxed.

$(30 \times 3.14 \times 104 \times 61) \div 1850 = 323$  ft. per min. for 1 H.P. per inch of width.

Samuel Webber (*Am. Mach.*, Feb. 22, 1894) reports a case of a belt 30 inches wide,  $\frac{3}{8}$  inch thick, running for six years at a velocity of 3900 feet per minute, on to a pulley 5 feet diameter, and transmitting 556 H.P. This gives a velocity of 210 feet per minute for 1 H.P. per inch of width. By Mr. Nagle's table of riveted belts this belt would be designed for 332 H.P. By Mr. Taylor's rule it would be used to transmit only 123 H.P.

The above may be taken as examples of what a belt may be made to do, but they should not be used as precedents in designing. It is not stated how much power was lost by the journal friction due to over-tightening of these belts.

**Belt Dressings.**—We advise that no belt dressing should be used except when the belt becomes dry and husky, and in such instances we recommend the use of a dressing. Where this is not used beef tallow at blood-warm temperature should be applied and then dried in either by artificial heat or the sun. The addition of beeswax to the tallow will be of some service if the belts are used in wet or damp places. Our experience convinces us that resin should never be used on leather belting. (Fayerweather & Ladew.)

Belts should not be soaked in water before oiling, and penetrating oils should but seldom be used, except occasionally when a belt gets very dry and husky from neglect. It may then be moistened a little, and have neat's-foot oil applied. Frequent applications of such oils to a new belt render the leather soft and flabby, thus causing it to stretch, and making it liable to run out of line. A composition of tallow and oil, with a little resin or beeswax, is better to use. Prepared castor-oil dressing is good, and may be applied with a brush or rag while the belt is running. (Alexander Bros.)

**Cement for Cloth or Leather.** (Molesworth.)—16 parts gutta-percha, 4 india-rubber, 2 pitch, 1 shellac, 2 linseed-oil, cut small, melted together and well mixed.

**Rubber Belting.**—The advantages claimed for rubber belting are perfect uniformity in width and thickness; it will endure a great degree of heat and cold without injury; it is also specially adapted for use in damp or wet places, or where exposed to the action of steam; it is very durable, and has great tensile strength, and when adjusted for service it has the most perfect hold on the pulleys, hence is less liable to slip than leather.

*Never use animal oil or grease on rubber belts, as it will greatly injure and soon destroy them.*

Rubber belts will be improved, and their durability increased, by putting on with a painter's brush, and letting it dry, a composition made of equal parts of red lead, black lead, French yellow, and litharge, mixed with boiled linseed-oil and japan enough to make it dry quickly. The effect of this will be to produce a finely polished surface. If, from dust or other cause, the belt should slip, it should be lightly moistened on the side next the pulley with boiled linseed-oil. (From circulars of manufacturers.)

The best conditions are large pulleys and high speeds, low tension and reduced width of belt. 4000 ft. per min. is not an excessive speed on proper sized pulleys.

H.P. of a 4-ply rubber belt = (length of arc of contact on smaller pulley in ft.  $\times$  width of belt in ins.  $\times$  revs. per min.)  $\div$  325. For a 5-ply belt multiply by  $1\frac{1}{3}$ , for a 6-ply by  $1\frac{3}{4}$ , for a 7-ply by 2, for an 8-ply by  $2\frac{1}{4}$ . When the proper weight of duck is used a 3- or 4-ply rubber belt is equal to a single leather belt and a 5- or 6-ply rubber to a double leather belt. When the arc of contact is  $180^\circ$ , H.P. of a 4-ply belt = width in ins.  $\times$  velocity in ft. per min.  $\div$  650. (Boston Belting Co.)

## GEARING.

### TOOTHED-WHEEL GEARING.

**Pitch, Pitch-circle, etc.**—If two cylinders with parallel axes are pressed together and one of them is rotated on its axis, it will drive the other by means of the friction between the surfaces. The cylinders may be considered as a pair of spur-wheels with an infinite number of very small teeth. If actual teeth are formed upon the cylinders, making alternate elevations and depressions in the cylindrical surfaces, the distance between the axes remaining the same, we have a pair of gear-wheels which will drive one another by pressure upon the faces of the teeth, if the teeth are properly shaped. In making the teeth the cylindrical surface may entirely disappear, but the position it occupied may still be considered as a cylindrical surface, which is called the "pitch-surface," and its trace on the end of the wheel, or on a plane cutting the wheel at right angles to its axis, is called the "pitch-circle" or "pitch-line." The diameter of this circle is called the pitch-diameter, and the distance from the face of one tooth to the corresponding face of the next tooth on the same wheel, measured on an arc of the pitch-circle, is called the "pitch of the tooth," or the circular pitch.

If two wheels having teeth of the same pitch are geared together so that their pitch-circles touch, it is a property of the pitch-circles that their diameters are proportional to the number of teeth in the wheels, and *vice versa*;

thus, if one wheel is twice the diameter (measured on the pitch-circle) of the other, it has twice as many teeth. If the teeth are properly shaped the linear velocity of the two wheels are equal, and the angular velocities, or speeds of rotation, are inversely proportional to the number of teeth and to the diameter. Thus the wheel that has twice as many teeth as the other will revolve just half as many times in a minute.

The "pitch," or distance measured on an arc of the pitch-circle from the face of one tooth to the face of the next, consists of two parts—the "thickness" of the tooth and the "space" between it and the next tooth. The space is larger than the thickness by a small amount called the "backlash," which is allowed for imperfections of workmanship. In finely cut gears the backlash may be almost nothing.

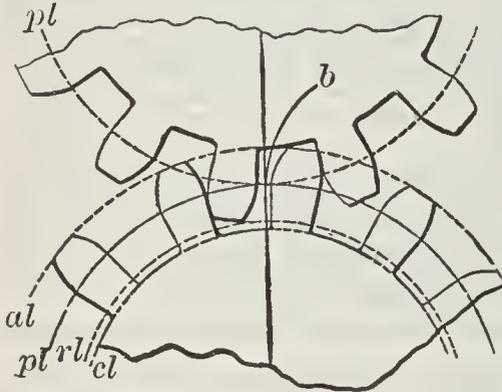

FIG. 153.

The length of a tooth in the direction of the radius of the wheel is called the "depth," and this is divided into two parts: First, the "addendum," the height of the tooth above the pitch-line; second, the "dedendum," the depth below the pitch line, which is an amount equal to the addendum of the mating gear. The depth of the space is usually given a little "clearance" to allow for inaccuracies of workmanship, especially in cast gears.

Referring to Fig. 153, *pl*, *pl* are the pitch-lines, *al* the addendum-line, *rl* the root-line or dedendum-line, *cl* the clearance-line, and *b* the backlash.

The addendum and dedendum are usually made equal to each other.

$$\text{Diametral pitch} = \frac{\text{No. of teeth}}{\text{diam. of pitch-circle in inches}} = \frac{\text{circular pitch}}{3.1416}$$

$$\text{Circular pitch} = \frac{\text{diam.} \times 3.1416}{\text{No. of teeth}} = \text{diametral pitch}$$

Some writers use the term diametral pitch to mean  $\frac{\text{diam.}}{\text{No. of teeth}} = \frac{\text{circular pitch}}{3.1416}$ , but the first definition is the more common and the more convenient. A wheel of 12 in. diam. at the pitch-circle, with 48 teeth is  $48/12 = 4$  diametral pitch, or simply 4 pitch. The circular pitch of the same wheel is  $\frac{12 \times 3.1416}{48} = .7854$ , or  $\frac{3.1416}{4} = .7854$  in.

**Relation of Diametral to Circular Pitch.**

Diametral Pitch.	Circular Pitch.	Diametral Pitch.	Circular Pitch.	Circular Pitch.	Diametral Pitch.	Circular Pitch.	Diametral Pitch.
1	3.142 in.	11	.286 in.	3	1.047	15/16	3.351
1½	2.094	12	.262	2½	1.257	7/8	3.590
2	1.571	14	.224	2	1.571	13/16	3.867
2¼	1.396	16	.196	17/8	1.676	3/4	4.189
2½	1.257	18	.175	1¾	1.795	11/16	4.570
2¾	1.142	20	.157	15/8	1.933	5/8	5.027
3	1.047	22	.143	1½	2.094	9/16	5.585
3½	.898	24	.131	1 7/16	2.185	1/2	6.283
4	.785	26	.121	1 3/8	2.285	7/16	7.181
5	.628	28	.112	1 5/16	2.394	3/8	8.378
6	.524	30	.105	1¼	2.513	5/16	10.053
7	.449	32	.098	1 3/16	2.646	1/4	12.566
8	.393	36	.087	1 1/8	2.793	3/16	16.755
9	.349	40	.079	1 1/16	2.957	1/8	25.133
10	.314	48	.065	1	3.142	1/16	50.266

Since circular pitch =  $\frac{\text{diam.} \times 3.1416}{\text{No. of teeth}}$ , diam. =  $\frac{\text{circ. pitch} \times \text{No. of teeth}}{3.1416}$ , which always brings out the diameter as a number with an inconvenient

fraction if the pitch is in even inches or simple fractions of an inch. By the diametral-pitch system this inconvenience is avoided. The diameter may be in even inches or convenient fractions, and the number of teeth is usually an even multiple of the number of inches in the diameter.

**Diameter of Pitch-line of Wheels from 10 to 100 Teeth of 1 in. Circular Pitch.**

No. Teeth.	Diam., in.										
10	3.183	26	8.276	41	13.051	56	17.825	71	22.600	86	27.375

For diameter of wheels of any other pitch than 1 in., multiply the figures in the table by the pitch. Given the diameter and the pitch, to find the number of teeth. Divide the diameter by the pitch, look in the table under diameter for the figure nearest to the quotient, and the number of teeth will be found opposite.

\* In terms of diametral pitch.

AUTHORITIES.—1. Sir Wm. Fairbairn. 2, 3. Clark, R. T. D.; "used by engineers in good practice." 4. Molesworth. 5, 6. Coleman Sellers: 5 for cast, 6 for cut wheels. 7, 8. Unwin. 9, 10. Leading American manufacturers of cut gears.

**The Chordal Pitch** (erroneously called "true pitch" by some authors) is the length of a straight line or chord drawn from centre to centre of two adjacent teeth. The term is now but little used.

Chordal pitch = diam. of pitch-circle  $\times$  sine of  $\frac{180^\circ}{\text{No. of teeth}}$ . Chordal pitch of a wheel of 10 in. pitch diameter and 10 teeth,  $10 \times \sin 18^\circ = 3.0902$  in. Circular pitch of same wheel = 3.1416. Chordal pitch is used with chain or sprocket wheels, to conform to the pitch of the chain.

**Formulae for Determining the Dimensions of Small Gears.**

(Brown & Sharpe Mfg. Co.)

$P$  = diametral pitch, or the number of teeth to one inch of diameter of pitch-circle;

$D'$ = diameter of pitch circle.....	Larger Wheel.	These wheels run together.
$D$ = whole diameter .....		
$N$ = number of teeth .....		
$V$ = velocity .....		
$d'$ = diameter of pitch-circle.....	Smaller Wheel.	
$d$ = whole diameter.....		
$n$ = number of teeth .....		
$v$ = velocity.....		

$a$  = distance between the centres of the two wheels;  
 $b$  = number of teeth in both wheels;  
 $t$  = thickness of tooth or cutter on pitch-circle;  
 $s$  = addendum;  
 $D''$  = working depth of tooth;  
 $f$  = amount added to depth of tooth for rounding the corners and for clearance;  
 $D'' + f$  = whole depth of tooth;  
 $\pi = 3.1416$ .  
 $P'$  = circular pitch, or the distance from the centre of one tooth to the centre of the next measured on the pitch-circle.

Formulae for a single wheel:

$$P = \frac{N + 2}{D}; \quad D' = \frac{D \times N}{N + 2}; \quad D'' = \frac{2}{P} = 2s; \quad s = \frac{1}{P} = \frac{P'}{\pi} = .3183P';$$

$$P = \frac{N}{D'}; \quad D' = \frac{N}{P}; \quad \frac{N}{N} = \frac{PD'}{PD - 2}; \quad s = \frac{D'}{N} = \frac{D}{N + 2};$$

$$P' = \frac{\pi}{P}; \quad D = \frac{N + 2}{P}; \quad f = \frac{t}{10}; \quad s + f = \frac{1}{P} \left( 1 + \frac{\pi}{20} \right) = .3685t$$

$$P = \frac{\pi}{P'}; \quad D = D' + \frac{2}{P}; \quad t = \frac{1.57}{P} = \frac{1}{2}P'.$$

Formulae for a pair of wheels:

$$b = 2aP; \quad n = \frac{PD'V}{v} \quad D = \frac{2a(N + 2)}{b};$$

$$N = \frac{nv}{V}; \quad v = \frac{PD'V}{n}; \quad d = \frac{2a(n + 2)}{b};$$

$$n = \frac{NV}{v}; \quad v = \frac{NV}{n}; \quad a = \frac{b}{2P};$$

$$N = \frac{bv}{v + V}; \quad V = \frac{nv}{N}; \quad a = \frac{D' + d'}{2};$$

$$n = \frac{bV}{v + V}; \quad D' = \frac{2av}{v + V}; \quad d' = \frac{2aV}{v + V}.$$

The following proportions of gear wheels are recommended by Prof. Coleman Sellers. (*Stevens Indicator*, April, 1892.)

**Proportions of Gear-wheels.**

Diametral Pitch.	Circular Pitch.	Outside of Pitch-line. $P \times .3$	Inside of Pitch-line.		Width of Space.	
			For Cast or Cut Bevels or for Cast Spurs. $P \times .4$	For Cut Spurs. $P \times .35$	For Cast Spurs or Bevels. $P \times .525$	For Cut Bevels or Spurs. $P \times .51$

Thickness of rim below root = depth of tooth.

**Width of Teeth.**—The width of the faces of teeth is generally made from 2 to 3 times the circular pitch — from 6.28 to 9.42 divided by the diametral pitch. There is no standard rule for width.

The following sizes are given in a stock list of cut gears in "Grant's Gears:"

Diameter pitch.....	3	4	6	8	12	16
Face, inches.....	3 and 4	$2\frac{1}{2}$	$1\frac{3}{4}$ and 2	$1\frac{1}{4}$ and $1\frac{1}{2}$	$\frac{3}{4}$ and 1	$\frac{1}{2}$ and $\frac{5}{8}$

The Walker Company give:

Circular pitch, in..	$\frac{1}{2}$	$\frac{5}{8}$	$\frac{3}{4}$	$\frac{7}{8}$	1	$1\frac{1}{2}$	2	$2\frac{1}{2}$	3	4	5	6
Face, in.....	$1\frac{1}{4}$	$1\frac{1}{2}$	$1\frac{3}{4}$	2	$2\frac{1}{2}$	$4\frac{1}{2}$	6	$7\frac{1}{2}$	9	12	16	20

**Rules for Calculating the Speed of Gears and Pulleys.**—The relations of the size and speed of driving and driven gear wheels are the same as those of belt pulleys. In calculating for gears, multiply or divide by the diameter of the pitch-circle or by the number of teeth, as may be required. In calculating for pulleys, multiply or divide by their diameter in inches.

If  $D$  = diam. of driving wheel,  $d$  = diam. of driven,  $R$  = revolutions per minute of driver,  $r$  = revs. per min. of driven,

$$R = rd \div D; \quad r = RD \div d; \quad D = dr \div R; \quad d = DR \div r.$$

If  $N$  = number of teeth of driver and  $n$  = number of teeth of driven,

$$N = nr \div R; \quad n = NR \div r; \quad R = rn \div N; \quad r = RN \div n.$$

To find the number of revolutions of the last wheel at the end of a train of spur-wheels, all of which are in a line and mesh into one another, when the revolutions of the first wheel and the number of teeth or the diameter of the first and last are given: Multiply the revolutions of the first wheel by its number of teeth or its diameter, and divide the product by the number of teeth or the diameter of the last wheel.

To find the number of teeth in each wheel for a train of spur-wheels, each to have a given velocity: Multiply the number of revolutions of the driving-wheel by its number of teeth, and divide the product by the number of revolutions each wheel is to make.

To find the number of revolutions of the last wheel in a train of wheels and pinions, when the revolutions of the first or driver, and the diameter, the teeth, or the circumference of all the drivers and pinions are given: Multiply the diameter, the circumference, or the number of teeth of all the driving-wheels together, and this continued product by the number of revolutions of the first wheel, and divide this product by the continued product of the diameter, the circumference, or the number of teeth of all the driven wheels, and the quotient will be the number of revolutions of the last wheel.

EXAMPLE.—1: A train of wheels consists of four wheels each 12 in. diameter of pitch-circle, and three pinions 4, 4, and 3 in. diameter. The large wheels are the drivers, and the first makes 36 revs. per min. Required the speed of the last wheel.

$$\frac{36 \times 12 \times 12 \times 12}{4 \times 4 \times 3} = 1296 \text{ rpm.}$$

2. What is the speed of the first large wheel if the pinions are the drivers, the 3-in. pinion being the first driver and making 36 revs. per min.?

$$\frac{36 \times 3 \times 4 \times 4}{12 \times 12 \times 12} = 1 \text{ rpm. Ans.}$$

**Milling Cutters for Interchangeable Gears.**—The Pratt & Whitney Co. make a series of cutters for cutting epicycloidal teeth. The number of cutters to cut from a pinion of 12 teeth to a rack is 24 for each pitch coarser than 10. The Brown & Sharpe Mfg. Co. make a similar series, and also a series for involute teeth, in which eight cutters are made for each pitch, as follows:

No.....	1.	2.	3.	4.	5.	6.	7.	8.
Will cut from	135	55	35	26	21	17	14	12
to	Rack	134	54	34	25	20	16	13

## FORMS OF THE TEETH.

In order that the teeth of wheels and pinions may run together smoothly and with a constant relative velocity, it is necessary that their working faces shall be formed of certain curves called odontoids. The essential property of these curves is that when two teeth are in contact the common normal to the tooth curves at their point of contact must pass through the pitch-point, or point of contact of the two pitch-circles. Two such curves are in common use—the cycloid and the involute.

**The Cycloidal Tooth.**—In Fig. 154 let  $PL$  and  $pl$  be the pitch-circles of two gear-wheels;  $GC$  and  $gc$  are two equal generating-circles, whose radii should be taken as not greater than one half of the radius of the smaller pitch-circle. If the circle  $gc$  be rolled to the left on the larger pitch-circle  $PL$ , the point  $O$  will describe an epicycloid,  $oefgh$ . If the other generating-circle  $GC$  be rolled to the right on  $PL$ , the point  $O$  will describe a hypocycloid  $oabcd$ . These two curves, which are tangent at  $O$ , form the two parts of a tooth curve for a gear whose pitch-circle is  $PL$ . The upper part  $oh$  is called the face and the lower part  $od$  is called the flank. If the same circles be rolled on the other pitch-circle  $pl$ , they will describe the curve for a tooth of the gear  $pl$ , which will work properly with the tooth on  $PL$ .

The cycloidal curves may be drawn without actually rolling the generating-circle, as follows: On the line  $PL$ , from  $O$ , step off and mark equal distances, as 1, 2, 3, 4, etc. From 1, 2, 3, etc., draw radial lines toward the centre of  $PL$ , and from 6, 7, 8, etc., draw radial lines from the same centre, but beyond  $PL$ . With the radius of the generating-circle, and with centres successively placed on these radial lines, draw arcs of circles tangent to  $PL$  at 1 2 3, 6 7 8, etc. With the dividers set to one of the equal divisions, as  $O_1$ ,

step off  $1a$  and  $6e$ ; step off two such divisions on the circle from  $2$  to  $b$ , and from  $7$  to  $f$ ; three such divisions from  $3$  to  $c$ , and from  $8$  to  $g$ ; and so on, thus locating the several points  $abcdH$  and  $efgk$ , and through these points draw the tooth curves.

The curves for the mating tooth on the other wheel may be found in like manner by drawing arcs of the generating-circle tangent at equidistant points on the pitch-circle  $pl$ .

The tooth curve of the face  $oh$  is limited by the addendum-line  $r$  or  $r_1$ ,

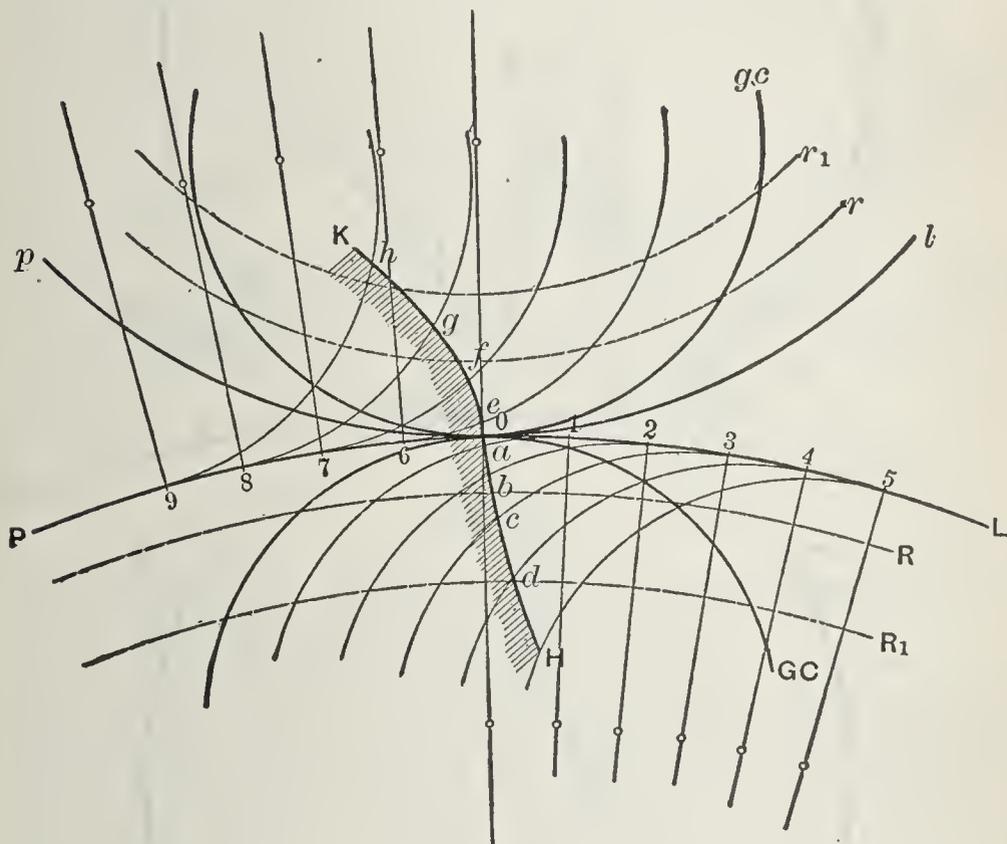

FIG. 154. 7

and that of the flank  $oH$  by the root curve  $R$  or  $R_1$ .  $R$  and  $r$  represent the root and addendum curves for a large number of small teeth, and  $R_1r$  the like curves for a small number of large teeth. The form or appearance of the tooth therefore varies according to the number of teeth, while the pitch-circle and the generating-circle may remain the same.

In the cycloidal system, in order that a set of wheels of different diameters but equal pitches shall all correctly work together, it is necessary that the generating-circle used for the teeth of all the wheels shall be the same, and it should have a diameter not greater than half the diameter of the pitch-line of the smallest wheel of the set. The customary standard size of the generating-circle of the cycloidal system is one having a diameter equal to the radius of the pitch-circle of a wheel having 12 teeth. (Some gear-makers adopt 15 teeth.) This circle gives a radial flank to the teeth of a wheel having 12 teeth. A pinion of 10 or even a smaller number of teeth can be made, but in that case the flanks will be undercut, and the tooth will not be as strong as a tooth with radial flanks. If in any case the describing circle be half the size of the pitch-circle, the flanks will be radial; if it be less, they will spread out toward the root of the tooth, giving a stronger form; but if greater, the flanks will curve in toward each other, whereby the teeth become weaker and difficult to make.

In some cases cycloidal teeth for a pair of gears are made with the generating-circle of each gear, having a radius equal to half the radius of its pitch-circle. In this case each of the gears will have radial flanks. This method makes a smooth working gear, but a disadvantage is that the wheels are not interchangeable with other wheels of the same pitch but different numbers of teeth.

The rack in the cycloidal system is equivalent to a wheel with an infinite number of teeth. The pitch is equal to the circular pitch of the mating gear. Both faces and flanks are cycloids formed by rolling the generating-circle of the mating gear-wheel on each side of the straight pitch-line of the rack.

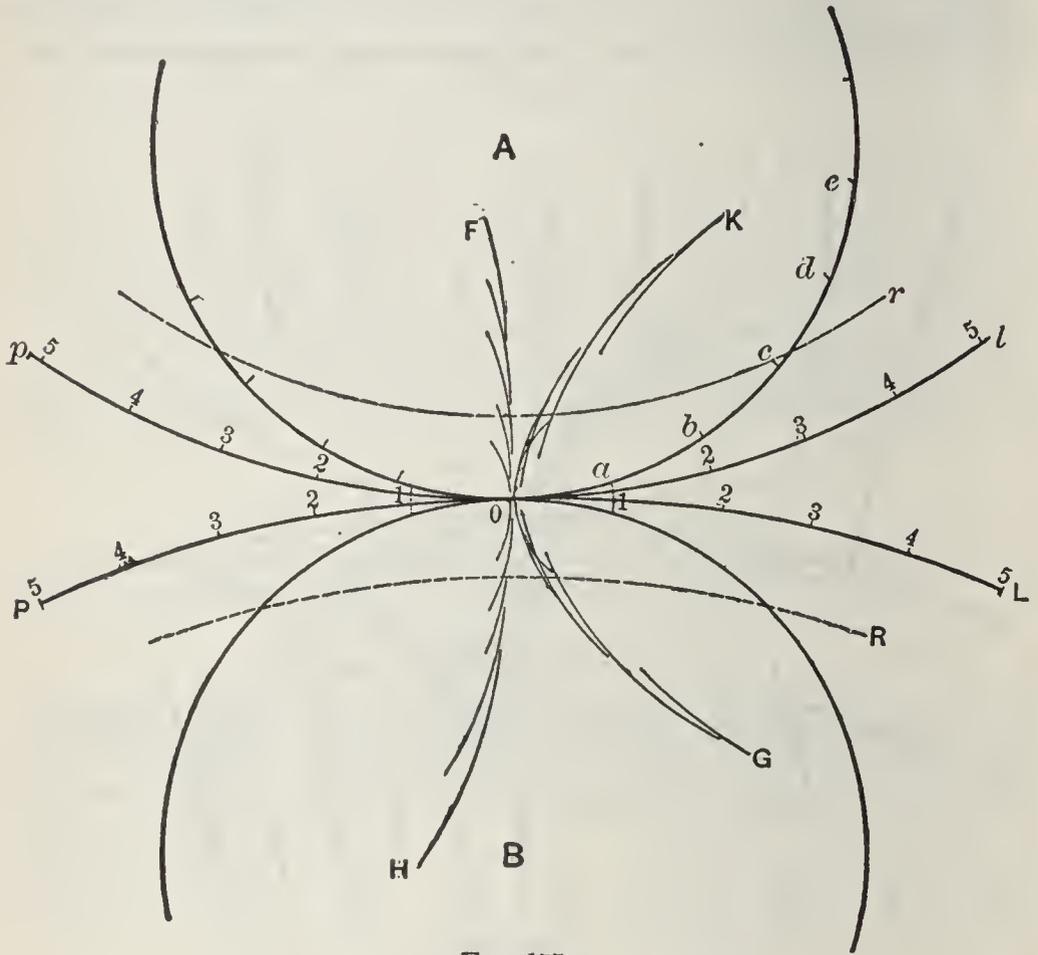

FIG. 155.

Another method of drawing the cycloidal curves is shown in Fig. 155. It is known as the method of tangent arcs. The generating-circles, as before, are drawn with equal radii, the length of the radius being less than half the radius of  $pl$ , the smaller pitch-circle. Equal divisions 1, 2, 3, 4, etc., are marked off on the pitch circles and divisions of the same length stepped off on one of the generating-circles, as  $oabc$ , etc. From the points 1, 2, 3, 4, 5 on the line  $po$ , with radii successively equal to the chord distances  $oa$ ,  $ob$ ,  $oc$ ,  $od$ ,  $oe$ , draw the five small arcs  $F$ . A line drawn through the outer edges of these small arcs, tangent to them all, will be the hypocycloidal curve for the flank of a tooth below the pitch-line  $pl$ . From the points 1, 2, 3, etc., on the line  $ol$ , with radii as before, draw the small arcs  $G$ . A line tangent to these arcs will be the epicycloid for the face of the same tooth for which the flank curve has already been drawn. In the same way, from centres on the line  $P_o$ , and  $oL$ , with the same radii, the tangent arcs  $H$  and  $K$  may be drawn, which will give the tooth for the gear whose pitch-circle is  $PL$ .

If the generating-circle had a radius just one half of the radius of  $pl$ , the hypocycloid  $F$  would be a straight line, and the flank of the tooth would have been radial.

**The Involute Tooth.**—In drawing the involute tooth curve, the angle of obliquity, or the angle which a common tangent to the teeth, when they are in contact at the pitch-point, makes with a line joining the centres of the wheels, is first arbitrarily determined. It is customary to take it at  $15^\circ$ . The pitch-lines  $pl$  and  $PL$  being drawn in contact at  $O$ , the line of obliquity  $AB$  is drawn through  $O$  normal to a common tangent to the tooth curves, or at the given angle of obliquity to a common tangent to the pitch-circles. In

the cut the angle is  $20^\circ$ . From the centres of the pitch-circles draw circles  $c$  and  $d$  tangent to the line  $AB$ . These circles are called base-lines or base-circles, from which the involutes  $F$  and  $K$  are drawn. By laying off convenient distances, 0, 1, 2, 3, which should each be less than  $1/10$  of the diameter of the base-circle, small arcs can be drawn with successively increasing radii, which will form the involute. The involute extends from the points  $F'$

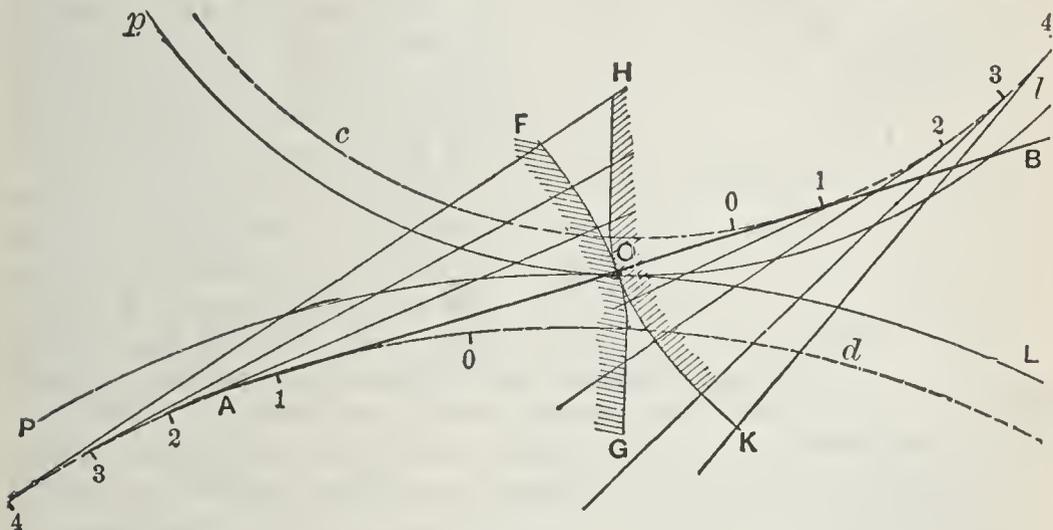

FIG. 156.

and  $K$  down to their respective base-circles, where a tangent to the involute becomes a radius of the circle, and the remainders of the tooth curves, as  $G$  and  $H$ , are radial straight lines.

In the involute system the customary standard form of tooth is one having an angle of obliquity of  $15^\circ$  (Brown and Sharpe use  $14\frac{1}{2}^\circ$ ), an addendum of about one third the circular pitch, and a clearance of about one eighth of the addendum. In this system the smallest gear of a set has 12 teeth, this being the smallest number of teeth that will gear together when made with this angle of obliquity. In gears with less than 30 teeth the points of the teeth must be slightly rounded over to avoid interference (see Grant's Teeth of Gears). All involute teeth of the same pitch and with the same angle of obliquity work smoothly together. The rack to gear with an involute-toothed wheel has straight faces on its teeth, which make an angle with the middle line of the tooth equal to the angle of obliquity, or in the standard form the faces are inclined at an angle of  $30^\circ$  with each other.

To draw the teeth of a rack which is to gear with an involute wheel (Fig. 157).—Let  $AB$  be the pitch-line of the rack and  $AI=I'I'$  the pitch. Through

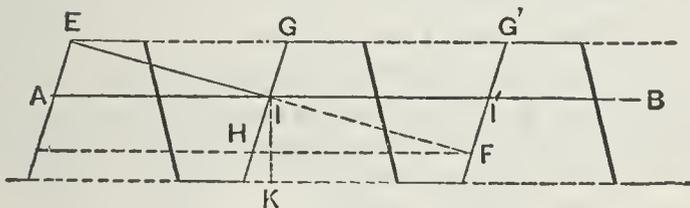

FIG. 157.

the pitch-point  $I$  draw  $EF$  at the given angle of obliquity. Draw  $AE$  and  $IF$  perpendicular to  $EF$ . Through  $E$  and  $F$  draw lines  $EGG'$  and  $FH$  parallel to the pitch-line.  $EGG'$  will be the addendum-line and  $HF$  the flank-line. From  $I$  draw  $IK$  perpendicular to  $AB$  equal to the greatest addendum in the set of wheels of the given pitch and obliquity plus an allowance for clearance equal to  $1/8$  of the addendum. Through  $K$ , parallel to  $AB$ , draw the clearance-line. The fronts of the teeth are planes perpendicular to  $EF$ , and the backs are planes inclined at the same angle to  $AB$  in the contrary direction. The outer half of the working face  $AE$  may be slightly curved. Mr. Grant makes it a circular arc drawn from a centre on the pitch-line

with a radius  $\approx 2\frac{1}{2}$  inches divided by the diametral pitch, or  $.67 \text{ in.} \times \text{cir-}$   
 cular pitch.

**To Draw an Angle of  $15^\circ$  without using a Protractor.**—From  $C$ , on the line  $AC$ , with radius  $AC$ , draw an arc  $AB$ , and from  $A$ , with the same radius, cut the arc at  $B$ . Bisect the arc  $BA$  by drawing small arcs at  $D$  from  $A$  and  $B$  as centres, with the same radius, which must be greater than one half of  $AB$ . Join  $DC$ , cutting  $BA$  at  $E$ . The angle  $ECA$  is  $30^\circ$ . Bisect the arc  $AE$  in like manner, and the angle  $FCA$  will be  $15^\circ$ .

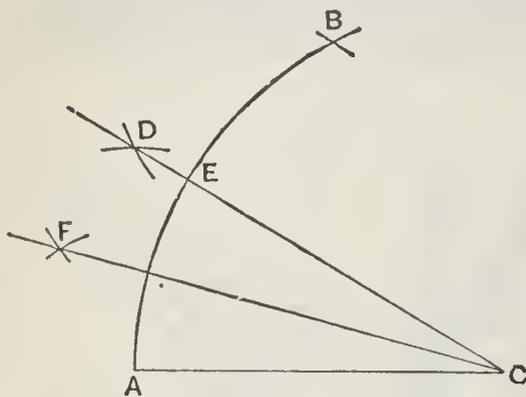

FIG. 158.

justed by moving the wheels farther from or nearer to each other, and may thus be adjusted so as to be no greater than is necessary to prevent jamming of the teeth.

The relative merits of cycloidal and involute-shaped teeth are still a subject of dispute, but there is an increasing tendency to adopt the involute tooth for all purposes.

Clark (R. T. D., p. 734) says: Involute teeth have the disadvantage of being too much inclined to the radial line, by which an undue pressure is exerted on the bearings.

Unwin (Elements of Machine Design, 8th ed., p. 265) says: The obliquity of action is ordinarily alleged as a serious objection to involute wheels. Its importance has perhaps been overrated.

George B. Grant (*Am. Mach.*, Dec. 26, 1885) says:

1. The work done by the friction of an involute tooth is always less than the same work for any possible epicycloidal tooth.
2. With respect to work done by friction, a change of the base from a gear of 12 teeth to one of 15 teeth makes an improvement for the epicycloid of less than one half of one per cent.
3. For the 12-tooth system the involute has an advantage of  $11\frac{1}{5}$  per cent, and for the 15-tooth system an advantage of  $\frac{3}{4}$  per cent.
4. That a maximum improvement of about one per cent can be accomplished by the adoption of any possible non-interchangeable radial flank tooth in preference to the 12-tooth interchangeable system.
5. That for gears of very few teeth the involute has a decided advantage.
6. That the common opinion among millwrights and the mechanical public in general in favor of the epicycloid is a prejudice that is founded on long-continued custom, and not on an intimate knowledge of the properties of that curve.

Wilfred Lewis (Proc. Engrs. Club of Phila., vol. x., 1893) says a strong reaction in favor of the involute system is in progress, and he believes that an involute tooth of  $22\frac{1}{2}^\circ$  obliquity will finally supplant all other forms.

**Approximation by Circular Arcs.**—Having found the form of the actual tooth-curve on the drawing-board, circular arcs may be found by trial which will give approximations to the true curves, and these may be

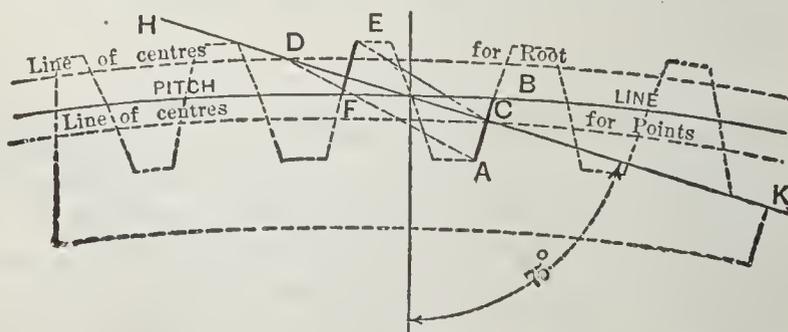

FIG. 159.

used in completing the drawing and the pattern of the gear-wheels. The root of the curve is connected to the clearance by a fillet, which should be as large as possible to give increased strength to the tooth, provided it is not large enough to cause interference.

Molesworth gives the following method of construction by circular arcs :

From the radial line at the edge of the tooth on the pitch-line, lay off the line  $HK$  at an angle of  $75^\circ$  with the radial line; on this line will be the centres of the root  $AB$  and the point  $EF$ . The lines struck from these centres are shown in thick lines. Circles drawn through centres thus found will give the lines in which the remaining centres will be. The radius  $DA$  for striking the root  $AB$  is = pitch + the thickness of the tooth. The radius  $CE$  for striking the point of the tooth  $EF$  = the pitch.

George B. Grant says : It is sometimes attempted to construct the curve by some handy method or empirical rule, but such methods are generally worthless.

**Stepped Gears.**—Two gears of the same pitch and diameter mounted side by side on the same shaft will act as a single gear. If one gear is keyed on the shaft so that the teeth of the two wheels are not in line, but the teeth of one wheel slightly in advance of the other, the two gears form a stepped gear. If mated with a similar stepped gear on a parallel shaft the number of teeth in contact will be twice as great as in an ordinary gear, which will increase the strength of the gear and its smoothness of action.

**Twisted Teeth.**—If a great number of very thin gears were placed together, one slightly in advance of the other, they would still act as a stepped gear. Continuing the subdivision until the thickness of each separate gear is infinitesimal, the faces of the teeth instead of being in steps take the form of a spiral or twisted surface, and we have a twisted gear. The twist may take any shape, and if it is in one direction for half the width of the gear and in the opposite direction for the other half, we have what is known as the herring-bone or double helical tooth. The obliquity of the twisted tooth if twisted in one direction causes an end thrust on the shaft, but if the herring-bone twist is used, the opposite obliquities neutralize each other. This form of tooth is much used in heavy rolling-mill practice, where great strength and resistance to shocks are necessary. They are frequently made of steel castings (Fig. 160). The angle of the tooth with a line parallel to the axis of the gear is usually  $30^\circ$ .

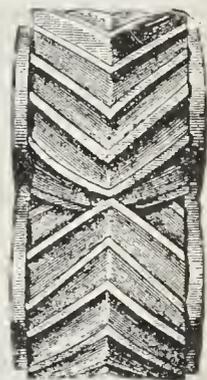

FIG. 160.

**Spiral Gears.**—If a twisted gear has a uniform twist it becomes a spiral gear. The line in which the pitch-surface intersects the face of the tooth is part of a helix drawn on the pitch-surface. A spiral wheel may be made with only one helical tooth wrapped around the cylinder several times, in which it becomes a screw or worm. If it has two or three teeth so wrapped, it is a double- or triple-threaded screw or worm. A spiral-gear meshing into a rack is used to drive the table of some forms of planing-machine.

**Worm-gearing.**—When the axes of two spiral gears are at right angles, and a wheel of one, two, or three threads works with a larger wheel of many threads, it becomes a worm-gear, or endless screw, the smaller

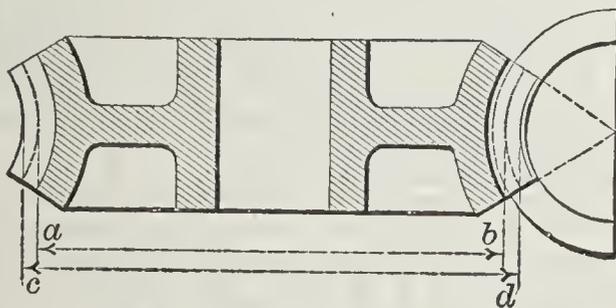

FIG. 161.

wheel or driver being called the worm, and the larger, or driven wheel, the worm-wheel. With this arrangement a high velocity ratio may be obtained with a single pair of wheels. For a one-threaded wheel the velocity ratio is

the number of teeth in the worm-wheel. The worm and wheel are commonly so constructed that the worm will drive the wheel, but the wheel will not drive the worm.

To find the diameter of a worm-wheel at the throat, number of teeth and pitch of the worm being given: Add 2 to the number of teeth, multiply the sum by 0.3183, and by the pitch of the worm in inches.

To find the number of teeth, diameter at throat and pitch of worm being given: Divide 3.1416 times the diameter by the pitch, and subtract 2 from the quotient.

In Fig. 161 *ab* is the diam. of the pitch-circle, *cd* is the diam. at the throat.

EXAMPLE.—Pitch of worm  $\frac{1}{4}$  in., number of teeth 70, required the diam. at the throat.  $(70 + 2) \times .3183 \times .25 = 5.73$  in.

**Teeth of Bevel-wheels.** (Rankine's Machinery and Millwork).—The teeth of a bevel-wheel have acting surfaces of the conical kind, generated by the motion of a line traversing the apex of the conical pitch-surface, while a point in it is carried round the traces of the teeth upon a spherical surface described about that apex.

The operations of drawing the traces of the teeth of bevel-wheels exactly, whether by involutes or by rolling curves, are in every respect analogous to those for drawing the traces of the teeth of spur-wheels; except that in the case of bevel-wheels all those operations are to be performed on the surface of a sphere described about the apex, instead of on a plane, substituting poles for centres and great circles for straight lines.

In consideration of the practical difficulty, especially in the case of large wheels, of obtaining an accurate spherical surface, and of drawing upon it when obtained, the following approximate method, proposed originally by Tredgold, is generally used:

Let *O*, Fig. 162, be the common apex of the pitch-cones, *OBI*, *OB'I*, of a pair of bevel-wheels; *OC*, *OC'*, the axes of those cones; *OI* their line of contact. Perpendicular to *OI* draw

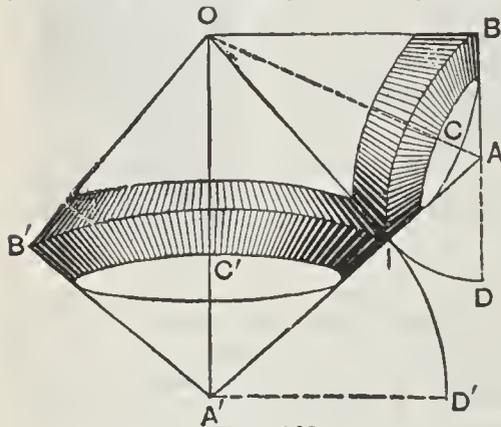

FIG. 162.

faces *ABI*, *A'B'I* are spread out flat. Describe the traces of teeth for the developed arcs as for a pair of spur-wheels, then wrap the developed arcs on the normal cones, so as to make them coincide with the pitch-circles, and trace the teeth on the conical surfaces.

For formulæ and instructions for designing bevel-gears, and for much other valuable information on the subject of gearing, see "Practical Treatise on Gearing," and "Formulas in Gearing," published by Brown & Sharpe Mfg Co.; and "Teeth of Gears," by George B. Grant, Lexington, Mass. The student may also consult Rankine's Machinery and Millwork, Reuleaux's Constructor, and Unwin's Elements of Machine Design. See also article on Gearing, by C. W. MacCord in App. Cyc. Mech., vol. ii.

**Annular and Differential Gearing.** (S. W. Balch., *Am. Mach.*, Aug. 24, 1893).—In internal gears the sum of the diameters of the describing circles for faces and flanks should not exceed the difference in the pitch diameters of the pinion and its internal gear. The sum may be equal to this difference or it may be less; if it is equal, the faces of the teeth of each wheel will drive the faces as well as the flanks of the teeth of the other wheel. The teeth will therefore make contact with each other at two points at the same time.

Cycloidal tooth-curves for interchangeable gears are formed with describing circles of about  $\frac{5}{8}$  the pitch diameter of the smallest gear of the series. To admit two such circles between the pitch-circles of the pinion and internal

gear the number of teeth in the internal gear should exceed the number in the pinion by 12 or more, if the teeth are of the customary proportions and curvature used in interchangeable gearing.

Very often a less difference is desirable, and the teeth may be modified in several ways to make this possible.

*First.* The tooth curves resulting from smaller describing circles may be employed. These will give teeth which are more rounding and narrower at their tops, and therefore not as desirable as the regular forms.

*Second.* The tips of the teeth may be rounded until they clear. This is a cut-and-try method which aims at modifying the teeth to such outlines as smaller describing circles would give.

*Third.* One of the describing circles may be omitted and one only used, which may be equal to the difference between the pitch-circles. This will permit the meshing of gears differing by six teeth. It will usually prove inexpedient to put wheels in inside gears that differ by much less than 12 teeth.

If a regular diametral pitch and standard tooth forms are determined on, the diameter to which the internal gear-blank is to be bored is calculated by subtracting 2 from the number of teeth, and dividing the remainder by the diametral pitch.

The tooth outlines are the match of a spur-gear of the same number of teeth and diametral pitch, so that the spur-gear will fit the internal gear as a punch fits its die, except that the teeth of each should fail to bottom in the tooth spaces of the other by the customary clearance of one tenth the thickness of the tooth.

Internal gearing is particularly valuable when employed in differential action. This is a mechanical movement in which one of the wheels is mounted on a crank so that its centre can move in a circle about the centre of the other wheel. Means are added to the device which restrain the wheel on the crank from turning over and confine it to the revolution of the crank.

The ratio of the number of teeth in the revolving wheel compared with the difference between the two will represent the ratio between the revolving wheel and the crank-shaft by which the other is carried. The advantage in accomplishing the change of speed with such an arrangement, as compared with ordinary spur-gearing, lies in the almost entire absence of friction and consequent wear of the teeth.

But for the limitation that the difference between the wheels must not be too small, the possible ratio of speed might be increased almost indefinitely, and one pair of differential gears made to do the service of a whole train of wheels. If the problem is properly worked out with bevel-gears this limitation may be completely set aside, and external and internal bevel-gears, differing by but a single tooth if need be, made to mesh perfectly with each other.

Differential bevel-gears have been used with advantage in mowing-machines. A description of their construction and operation is given by Mr. Balch in the article from which the above extracts are taken.

**EFFICIENCY OF GEARING.**

An extensive series of experiments on the efficiency of gearing, chiefly worm and spiral gearing, is described by Wilfred Lewis in Trans. A. S. M. E., vii. 273. The average results are shown in a diagram, from which the following approximate average figures are taken :

EFFICIENCY OF SPUR, SPIRAL, AND WORM GEARING.

Gearing.	Pitch.	Velocity at Pitch line in feet per min.				
		3	10	40	100	200
Spur pinion.....		.90	.935	.97	.98	.985
Spiral pinion.....	45°	.81	.87	.93	.955	.965
“ “ .....	30	.75	.815	.89	.93	.945
“ “ .....	20	.67	.75	.845	.90	.92
“ “ .....	15	.61	.70	.805	.87	.90
Spiral pinion or worm.....	10	.51	.615	.74	.82	.86
“ “ “ .....	7	.43	.53	.72	.765	.815
“ “ “ .....	5	.34	.43	.60	.70	.765

The experiments showed the advantage of spur-gearing over all other kinds in both durability and efficiency. The variation from the mean results rarely exceeded 5% in either direction, so long as no cutting occurred, but the variation became much greater and very irregular as soon as cutting began. The loss of power varies with the speed, the pressure, the temperature, and the condition of the surfaces. The excessive friction of worm and spiral gearing is largely due to the end thrust on the collars of the shaft. This may be considerably reduced by roller-bearings for the collars.

When two worms with opposite spirals run in two spiral worm-gears that also work with each other, and the pressure on one gear is opposite that on the other, there is no thrust on the shaft. Even with light loads a worm will begin to heat and cut if run at too high a speed, the limit for safe working being a velocity of the rubbing surfaces of 200 to 300 ft. per minute, the former being preferable where the gearing has to work continuously. The wheel teeth will keep cool, as they form part of a casting having a large radiating surface; but the worm itself is so small that its heat is dissipated slowly. Whenever the heat generated increases faster than it can be conducted and radiated away, the cutting of the worm may be expected to begin. A low efficiency for a worm-gear means more than the loss of power, since the power which is lost reappears as heat and may cause the rapid destruction of the worm.

Unwin (Elements of Machine Design, p. 294) says: The efficiency is greater the less the radius of the worm. Generally the radius of the worm = 1.5 to 3 times the pitch of the thread of the worm or the circular pitch of the worm-wheel. For a one-threaded worm the efficiency is only  $\frac{2}{5}$  to  $\frac{1}{4}$ ; for a two-threaded worm,  $\frac{4}{7}$  to  $\frac{2}{5}$ ; for a three-threaded worm,  $\frac{2}{3}$  to  $\frac{1}{2}$ . Since so much work is wasted in friction it is not surprising that the wear is excessive. The following table gives the calculated efficiencies of worm-wheels of 1, 2, 3, and 4 threads and ratios of radius of worm to pitch of teeth of from 1 to 6, assuming a coefficient of friction of 0.15:

No. of Threads.	Radius of Worm $\div$ Pitch.								
	1	$1\frac{1}{4}$	$1\frac{1}{2}$	$1\frac{3}{4}$	2	$2\frac{1}{2}$	3	4	6
1	.50	.44	.40	.36	.33	.28	.25	.20	.14
2	.67	.62	.57	.53	.50	.44	.40	.33	.25
3	.75	.70	.67	.63	.60	.55	.50	.43	.33
4	.80	.76	.73	.70	.67	.62	.57	.50	.40

### STRENGTH OF GEAR-TEETH.

The strength of gear-teeth and the horse-power that may be transmitted by them depend upon so many variable and uncertain factors that it is not surprising that the formulas and rules given by different writers show a wide variation. In 1879 John H. Cooper (*Jour. Frank. Inst.*, July, 1879) found that there were then in existence about 48 well-established rules for horse-power and working strength, differing from each other in extreme cases about 500%. In 1886 Prof. Wm. Harkness (*Proc. A. A. A. S.* 1886), from an examination of the bibliography of the subject, beginning in 1796, found that according to the constants and formulæ used by various authors there were differences of 15 to 1 in the power which could be transmitted by a given pair of geared wheels. The various elements which enter into the constitution of a formula to represent the working strength of a toothed wheel are the following: 1. The strength of the metal, usually cast iron, which is an extremely variable quantity. 2. The shape of the tooth, and especially the relation of its thickness at the root or point of least strength to the pitch and to the length. 3. The point at which the load is taken to be applied, assumed by some authors to be at the pitch-line, by others at the extreme end, along the whole face, and by still others at a single outer corner. 4. The consideration of whether the total load is at any time received by a single tooth or whether it is divided between two teeth. 5. The influence of velocity in causing a tendency to break the teeth by shock. 6. The factor of safety assumed to cover all the uncertainties of the other elements of the problem.

Prof. Harkness, as a result of his investigation, found that all the formulæ on the subject might be expressed in one of three forms, viz.:

$$\text{Horse-power} = CVpf, \text{ or } CVp^2, \text{ or } CVp^2f;$$

in which  $C$  is a coefficient,  $V$  = velocity of pitch-line in feet per second,  $p$  = pitch in inches, and  $f$  = face of tooth in inches.

From an examination of precedents he proposed the following formula for cast-iron wheels:

$$\text{H.P.} = \frac{0.910Vpf}{\sqrt{1 + 0.65V}}$$

He found that the teeth of chronometer and watch movements were subject to stresses four times as great as those which any engineer would dare to use in like proportion upon cast-iron wheels of large size.

It appears that all of the earlier rules for the strength of teeth neglected the consideration of the variations in their form; the breaking strength, as said by Mr. Cooper, being based upon the thickness of the teeth at the pitch-line or circle, as if the thickness at the root of the tooth were the same in all cases as it is at the pitch-line.

Wilfred Lewis (Proc. Eng'rs Club, Phila., Jan. 1893; *Am. Mach.*, June 22, 1893) seems to have been the first to use the form of the tooth in the construction of a working formula and table. He assumes that in well-constructed machinery the load can be more properly taken as well distributed across the tooth than as concentrated in one corner, but that it cannot be safely taken as concentrated at a maximum distance from the root less than the extreme end of the tooth. He assumes that the whole load is taken upon one tooth, and considers the tooth as a beam loaded at one end, and from a series of drawings of teeth of the involute, cycloidal, and radial flank systems, determines the point of weakest cross-section of each, and the ratio of the thickness at that section to the pitch. He thereby obtains the general formula,

$$W = spfy;$$

in which  $W$  is the load transmitted by the teeth, in pounds;  $s$  is the safe working stress of the material, taken at 8000 lbs. for cast iron, when the working speed is 100 ft. or less per minute;  $p$  = pitch;  $f$  = face, in inches;  $y$  = a factor depending on the form of the tooth, whose value for different cases is given in the following table:

No. of Teeth.	Factor for Strength, $y$ .			No. of Teeth.	Factor for Strength, $y$ .		
	Involute 20° Obliquity.	Involute 15° and Cycloidal	Radial Flanks.		Involute 20° Obliquity.	Involute 15° and Cycloidal	Radial Flanks.
12	.078	.067	.052	27	.111	.100	.064
13	.083	.070	.053	30	.114	.102	.065
14	.088	.072	.054	34	.118	.104	.066
15	.092	.075	.055	38	.122	.107	.067
16	.094	.077	.056	43	.126	.110	.068
17	.096	.080	.057	50	.130	.112	.069
18	.098	.083	.058	60	.134	.114	.070
19	.100	.087	.059	75	.138	.116	.071
20	.102	.090	.060	100	.142	.118	.072
21	.104	.092	.061	150	.146	.120	.073
23	.106	.094	.062	300	.150	.122	.074
25	.108	.097	.063	Rack.	.154	.124	.075

SAFE WORKING STRESS,  $s$ , FOR DIFFERENT SPEEDS.

Speed of Teeth in ft. per minute.	100 or less.	200	300	600	900	1200	1800	2400
Cast iron.....	8000	6000	4800	4000	3000	2400	2000	1700
Steel.....	20000	15000	12000	10000	7500	6000	5000	4300

The values of  $s$  in the above table are given by Mr. Lewis tentatively, in the absence of sufficient data upon which to base more definite values, but they have been found to give satisfactory results in practice.

Mr. Lewis gives the following example to illustrate the use of the tables: Let it be required to find the working strength of a 12-toothed pinion of 1-inch pitch,  $2\frac{1}{2}$ -inch face, driving a wheel of 60 teeth at 100 feet or less per minute, and let the teeth be of the 20-degree involute form. In the formula  $W = spfy$  we have for a cast-iron pinion  $s = 8000$ ,  $pf = 2.5$ , and  $y = .078$ ; and multiplying these values together, we have  $W = 1560$  pounds. For the wheel we have  $y = .134$  and  $W = 2680$  pounds.

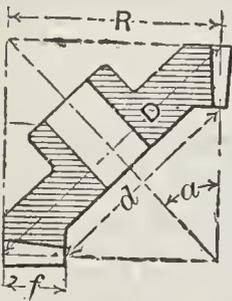

FIG. 163.

The cast-iron pinion is, therefore, the measure of strength; but if a steel pinion be substituted we have  $s = 20,000$  and  $W = 3900$  pounds, in which combination the wheel is the weaker, and it therefore becomes the measure of strength.

For bevel-wheels Mr. Lewis gives the following, referring to Fig. 163:  $D =$  large diameter of bevel;  $d =$  small diameter of bevel;  $p =$  pitch at large diameter;  $n =$  actual number of teeth;  $f =$  face of bevel;  $N =$  formative number of teeth  $= n \times \secant\ a$ , or the number corresponding to radius  $R$ ;  $y =$  factor depending upon shape of teeth and formative number  $N$ ;  $W =$  working load on teeth.

$$W = spfy \frac{D^3 - d^3}{3D^2(D - d)}; \text{ or, more simply, } W = spfy \frac{d}{D},$$

which gives almost identical results when  $d$  is not less than  $\frac{2}{3} D$ , as is the case in good practice.

In *Am. Mach.*, June 22, 1893, Mr. Lewis gives the following formulæ for the working strength of the three systems of gearing, which agree very closely with those obtained by use of the table:

For involute, 20° obliquity,  $W = spf \left( .154 - \frac{.912}{n} \right);$

For involute 15°, and cycloidal,  $W = spf \left( .124 - \frac{.684}{n} \right);$

For radial flank system,  $W = spf \left( .075 - \frac{.276}{n} \right);$

in which the factor within the parenthesis corresponds to  $y$  in the general formula. For the horse-power transmitted, Mr. Lewis's general formula

$W = spfy, = \frac{33,000 \text{ H.P.}}{v}$ , may take the form  $\text{H.P.} = \frac{spf y v}{33,000}$ , in which  $v =$  velocity in feet per minute; or since  $v = d\pi \times \text{rpm.} + 12 = .2618d \times \text{rpm.}$ , in which  $d =$  diameter in inches and rpm. = revolutions per minute,

$$\text{H.P.} = \frac{Wv}{33,000} = \frac{spf y \times d \times \text{rpm.}}{126,050} = .000007933dspf y \times \text{rpm.}$$

It must be borne in mind, however, that in the case of machines which consume power intermittently, such as punching and shearing machines, the gearing should be designed with reference to the maximum load  $W$ , which can be brought upon the teeth at any time, and not upon the average horse-power transmitted.

**Comparison of the Harkness and Lewis Formulas.**—Take an average case in which the safe working strength of the material,  $s = 6000$ ,  $v = 200$  ft. per min., and  $y = .100$ , the value in Mr. Lewis's table for an involute tooth of 15° obliquity, or a cycloidal tooth, the number of teeth in the wheel being 27.

$$\text{H.P.} = \frac{spf y v}{33,000} = \frac{6000pfv \times .100}{33,000} = \frac{pfv}{55} = 1.091pfV,$$

if  $V$  is taken in feet per second.

Prof. Harkness gives  $\text{H.P.} = \frac{0.910Vpf}{\sqrt{1 + 0.65V}}$ . If the  $V$  in the denominator

be taken at 200  $v = 3\frac{1}{2}$  feet per second,  $\sqrt{1 + 0.65V} = \sqrt{3.167} = 1.78$ , and H.P. =  $\frac{.910}{1.78} Vpf = .571pfV$ , or about 52% of the result given by Mr. Lewis's formula. This is probably as close an agreement as can be expected, since Prof. Harkness derived his formula from an investigation of ancient precedents and rule-of-thumb practice, largely with common cast gears, while Mr. Lewis's formula was derived from considerations of modern practice with machine-moulded and cut gears.

Mr. Lewis takes into consideration the reduction in working strength of a tooth due to increase in velocity by the figures in his table of the values of the safe working stress  $s$  for different speeds. Prof. Harkness gives expression to the same reduction by means of the denominator of his formula,  $\sqrt{1 + 0.65V}$ . The decrease in strength as computed by this formula is somewhat less than that given in Mr. Lewis's table, and as the figures given in the table are not based on accurate data, a mean between the values given by the formula and the table is probably as near to the true value as may be obtained from our present knowledge. The following table gives the values for different speeds according to Mr. Lewis's table and Prof. Harkness's formula, taking for a basis a working stress  $s$ , for cast-iron 8000, and for steel 20,000 lbs. at speeds of 100 ft. per minute and less:

$v$ = speed of teeth, ft. per min..	100	200	300	600	900	1200	1800	2400
$V$ = " " ft. per sec..	$1\frac{2}{3}$	$3\frac{1}{3}$	5	10	15	20	30	40
Safe stress $s$ , cast-iron, Lewis...	8000	6000	4800	4000	3000	2400	2000	1700
Relative do., $s \div 8000$ .....	1	.75	.6	.5	.375	.3	.25	.2125
$= 1 \div \sqrt{1 + 0.65V}$ .....	.6930	.5621	.4850	.3650	.3050	.2672	.2208	.1924
Relative val. $c \div .693$ .....	1	.811	.700	.526	.439	.385	.318	.277
$s_1 = 8000 \times (c \div .693)$ .....	8000	6438	5600	4208	3512	3080	2544	2216
Mean of $s$ and $s_1$ , cast-iron = $s_2$ .	8000	6200	5200	4100	3300	2700	2300	2000
" " " for steel = $s_3$ .	20000	15500	13000	10300	8100	6800	5700	4900
Safe stress for steel, Lewis.....	20000	15000	12000	10000	7500	6000	5000	4300

Comparing the two formulæ for the case of  $s = 8000$ , corresponding to a speed of 100 ft. per min., we have

Harkness: H.P. =  $1 \div \sqrt{1 + 0.65V} \times .910Vpf = .695 \times .91 \times 1\frac{2}{3}pf = 1.051pf$

Lewis: H.P. =  $\frac{spfyv}{33,000} = \frac{spfyV}{550} = \frac{8000 \times 1\frac{2}{3}pfy}{550} = 24.24pfy$ .

In which  $y$  varies according to the shape and number of the teeth.

- For radial-flank gear with 12 teeth  $y = .052$ ;  $24.24pfy = 1.260pf$ ;
- For 20° involute, 19 teeth, or 15° inv., 27 teeth  $y = .100$ ;  $24.24pfy = 2.424pf$ ;
- For 20° involute, 300 teeth  $y = .150$ ;  $24.24pfy = 3.636pf$ .

Thus the weakest-shaped tooth, according to Mr. Lewis, will transmit 20 per cent more horse-power than is given by Prof. Harkness's formula, in which the shape of the tooth is not considered, and the average-shaped tooth, according to Mr. Lewis, will transmit more than double the horse-power given by Prof. Harkness's formula.

**Comparison of Other Formulæ.**—Mr. Cooper, in summing up his examination, selected an old English rule, which Mr. Lewis considers as a passably correct expression of good general averages, viz. :  $X = 2000pf$ ,  $X$  = breaking load of tooth in pounds,  $p$  = pitch,  $f$  = face. If a factor of safety of 10 be taken, this would give for safe working load  $W = 200pf$ .

George B. Grant, in his Teeth of Gears, page 33. takes the breaking load at  $3500pf$ , and, with a factor of safety of 10, gives  $W = 350pf$ .

Nystrom's Pocket-Book, 20th ed., 1891, says : "The strength and durability of cast-iron teeth require that they shall transmit a force of 80 lbs. per inch of pitch and per inch breadth of face." This is equivalent to  $W = 80pf$ , or only 40% of that given by the English rule.

F. A. Halsey (Clark's Pocket Book) gives a table calculated from the formula  $H.P. = pfd \times \text{rpm.} \div 850$ .

Jones & Laughlins give H.P. =  $pfd \times \text{rpm.} \div 550$ .

These formulæ transformed give  $W = 128pf$  and  $W = 218pf$ , respectively.

Unwin, on the assumption that the load acts on the corners of the teeth, derives a formula  $p = K \sqrt{W}$ , in which  $K$  is a coefficient derived from existing wheels, its values being: for slowly moving gearing not subject to much vibration or shock  $K = .04$ ; in ordinary mill-gearing, running at greater speed and subject to considerable vibration,  $K = .05$ ; and in wheels subjected to excessive vibration and shock, and in mortise gearing,  $K = .06$ . Reduced to the form  $W = Cpf$ , assuming that  $f = 2p$ , these values of  $K$  give  $W = 262pf$ ,  $200pf$ , and  $139pf$ , respectively.

Unwin also gives the following formula, based on the assumption that the pressure is distributed along the edge of the tooth:  $p = K_1 \sqrt{\frac{p}{f}} \sqrt{W}$ ,

where  $K_1 =$  about .0707 for iron wheels and .0848 for mortise wheels when the breadth of face is not less than twice the pitch. For the case of  $f = 2p$  and the given values of  $K_1$  this reduces to  $W = 200pf$  and  $W = 139pf$ , respectively.

Box, in his Treatise on Mill Gearing, gives H.P. =  $\frac{12p^2f \sqrt{dn}}{1000}$ , in which  $n$  = number of revolutions per minute. This formula differs from the more modern formulæ in making the H.P. vary as  $p^2f$ , instead of as  $pf$ , and in this respect it is no doubt incorrect.

Making the H.P. vary as  $\sqrt{dn}$  or as  $\sqrt{v}$ , instead of directly as  $v$ , makes the velocity a factor of the working strength as in the Harkness and Lewis formulæ, the relative strength varying as  $\frac{\sqrt{v}}{v}$ , or as  $\frac{1}{\sqrt{v}}$ , which for different velocities is as follows:

Speed of teeth in ft. per min., $v$	= 100	200	300	600	900	1200	1800	2400
Relative strength	= 1	.707	.574	.408	.333	.289	.236	.204

Showing a somewhat more rapid reduction than is given by Mr. Lewis.

For the purpose of comparing different formulæ they may in general be reduced to either of the following forms:

$$\text{H.P.} = Cpfv, \quad \text{H.P.} = C_1 pfd \times \text{rpm.}, \quad W = cpf,$$

in which  $p$  = pitch,  $f$  = face,  $d$  = diameter, all in inches;  $v$  = velocity in feet per minute, rpm. revolutions per minute, and  $C$ ,  $C_1$  and  $c$  coefficients. The formulæ for transformation are as follows:

$$\text{H.P.} = \frac{Wv}{33000} = \frac{W \times d \times \text{rpm.}}{126,050};$$

$$W = \frac{33,000 \text{ H.P.}}{v} = \frac{126,050 \text{ H.P.}}{d \times \text{rpm.}} = 33,000Cpf; \quad pf = \frac{\text{H.P.}}{Cv} = \frac{\text{H.P.}}{C_1 d \times \text{rpm.}} = \frac{W}{c}.$$

$$C_1 = .2618C; \quad c = 33,000C; \quad C = 3.82C_1, = \frac{c}{33,000}; \quad c = 126,050C_1.$$

In the Lewis formula  $C$  varies with the form of the tooth and with the speed, and is equal to  $sy \div 33,000$ , in which  $y$  and  $s$  are the values taken from the table, and  $c = sy$ .

In the Harkness formula  $C$  varies with the speed and is equal to  $\frac{910}{\sqrt{1+0.65V}}$  ( $V$  being in feet per second), =  $\frac{.01517}{\sqrt{1+.011v}}$ .

In the Box formula  $C$  varies with the pitch and also with the velocity, and equals  $\frac{12p \sqrt{d} \times \text{rpm.}}{1000v} = .02345 \frac{p}{\sqrt{v}}$ .  $c = 33,000C = 774 \frac{p}{\sqrt{v}}$ .

For  $v = 100$  ft. per min.  $C = 77.4p$ ; for  $v = 600$  ft. per minute  $c = 31.6p$ . In the other formulæ considered  $C$ ,  $C_1$ , and  $c$  are constants. Reducing the several formulæ to the form  $W = cpf$ , we have the following:

COMPARISON OF DIFFERENT FORM LÆ FOR STRENGTH OF GEAR-TEETH.

Safe working pressure per inch pitch and per inch of face, or value of  $c$  in formula  $W = cpf$ :

	$v = 100$ ft. per min.	$v = 600$ ft. per min.
Lewis: Weak form of tooth, radial flank, 12 teeth... $c = 416$	416	208
Medium tooth, inv. $15^\circ$ , or cycloid, 27 teeth.. $c = 800$	800	400
Strong form of tooth, inv. $20^\circ$ , 300 teeth..... $c = 1200$	1200	600
Harkness: Average tooth..... $c = 347$	347	184
Box: Tooth of 1 inch pitch..... $c = 77.4$	77.4	31.6
" " " 3 inches pitch..... $c = 232$	232	95

Various, in which  $c$  is independent of form and speed: Old English rule,  $c = 200$ ; Grant,  $c = 350$ ; Nystrom,  $c = 80$ ; Halsey,  $c = 128$ ; Jones & Laughlins,  $c = 218$ ; Unwin,  $c = 262, 200, \text{ or } 139$ , according to speed, shock, and vibration.

The value given by Nystrom and those given by Box for teeth of small pitch are so much smaller than those given by the other authorities that they may be rejected as having an entirely unnecessary surplus of strength. The values given by Mr. Lewis seem to rest on the most logical basis, the form of the teeth as well as the velocity being considered; and since they are said to have proven satisfactory in an extended machine practice, they may be considered reliable for gears that are so well made that the pressure bears along the face of the teeth instead of upon the corners. For rough ordinary work the old English rule  $W = 200pf$  is probably as good as any, except that the figure 200 may be too high for weak forms of tooth and for high speeds.

The formula  $W = 200pf$  is equivalent to H.P. =  $\frac{pfd \times \text{rpm.}}{630} = \frac{pfv}{165}$ , or

H.P. =  $.0015873pfd \times \text{rpm.} = .006063pfv$ .

**Maximum Speed of Gearing.**—A. Towler, *Eng'g*, April 19, 1889, p. 388, gives the maximum speeds at which it was possible under favorable conditions to run toothed gearing safely as follows:

	Ft. per min.
Ordinary cast-iron wheels.....	1800
Helical " " " .....	2400
Mortise " " " .....	2400
Ordinary cast-steel wheels.....	2600
Helical " " " .....	3000
Special cast-iron machine-cut wheels.....	3000

Prof. Coleman Sellers (*Stevens Indicator*, April, 1892) recommends that gearing be not run over 1200 ft. per minute, to avoid great noise. The Walker Company, Cleveland, O., say that 2200 ft. per min. for iron gears and 3000 ft. for wood and iron (mortise gears) are excessive, and should be avoided if possible. The Corliss engine at the Philadelphia Exhibition (1876) had a fly wheel 30 ft. in diameter running 35 rpm. geared into a pinion 12 ft. diam. The speed of the pitch-line was 3300 ft. per min.

**A Heavy Machine-cut Spur-gear** was made in 1891 by the Walker Company, Cleveland, O., for a diamond mine in South Africa, with dimensions as follows: Number of teeth, 192; pitch diameter, 30' 6.66"; face, 30"; pitch, 6"; bore, 27"; diameter of hub, 9' 2"; weight of hub, 15 tons; and total weight of gear,  $66\frac{3}{4}$  tons. The rim was made in 12 segments, the joints of the segments being fastened with two bolts each. The spokes were bolted to the middle of the segments and to the hub with four bolts in each end.

**Frictional Gearing.**—In frictional gearing the wheels are toothless, and one wheel drives the other by means of the friction between the two surfaces which are pressed together. They may be used where the power to be transmitted is not very great; when the speed is so high that toothed wheels would be noisy; when the shafts require to be frequently put into and out of gear or to have their relative direction of motion reversed; or when it is desired to change the velocity-ratio while the machinery is in motion, as in the case of disk friction-wheels for changing the feed in machine tools.

Let  $P$  = the normal pressure in pounds at the line of contact by which two wheels are pressed together.  $T$  = tangential resistance of the driven wheel at the line of contact,  $f$  = the coefficient of friction,  $V$  = the velocity of the pitch-surface in feet per second, and H.P. = horse-power; then  $T$  may be equal to or less than  $fP$ ; H.P. =  $TV \div 550$ . The value of  $f$  for

metal on metal may be taken at .15 to .20; for wood on metal, .25 to .30; and for wood on compressed paper, .20. The tangential driving force  $T$  may be as high as 80 lbs. per inch width of face of the driving surface, but this is accompanied by great pressure and friction on the journal-bearings.

In frictional grooved gearing circumferential wedge-shaped grooves are cut in the faces of two wheels in contact. If  $P$  = the force pressing the wheels together, and  $N$  = the normal pressure on all the grooves,  $P = N (\sin a + f \cos a)$ , in which  $2a$  = the inclination of the sides of the grooves, and the maximum tangential available force  $T = fN$ . The inclination of the sides of the grooves to a plane at right angles to the axis is usually  $30^\circ$ .

**Frictional Grooved Gearing.**—A set of friction-gears for transmitting 150 H.P. is on a steam-dredge described in Proc. Inst. M. E., July, 1888. Two grooved pinions of 54 in. diam., with 9 grooves of  $1\frac{3}{4}$  in. pitch and angle of  $40^\circ$  cut on their face, are geared into two wheels of  $127\frac{1}{2}$  in. diam. similarly grooved. The wheels can be thrown in and out of gear by levers operating eccentric bushes on the large wheel-shaft. The circumferential speed of the wheels is about 500 ft. per min. Allowing for engine-friction, if half the power is transmitted through each set of gears the tangential force at the rims is about 3960 lbs., requiring, if the angle is  $40^\circ$  and the coefficient of friction 0.18, a pressure of 7524 lbs. between the wheels and pinion to prevent slipping.

The wear of the wheels proving excessive, the gears were replaced by spur-gear wheels and brake-wheels with steel brake-bands, which arrangement has proven more durable than the grooved wheels. Mr. Daniel Adamson states that if the frictional wheels had been run at a higher speed the results would have been better, and says they should run at least 30 ft. per second.

HOISTING AND CONVEYING.

**Approximate Weight and Strength of Cordage.** (Boston and Lockport Block Co.)—See also pages 339 to 345.

No. 1 was Weston's triplex block; No. 3, Weston's differential; No. 4, Weston's imported. The others were from different makers, whose names are not given. All the blocks were of one-ton capacity.

**Proportions of Hooks.**—The following formulæ are given by Henry R. Towne, in his Treatise on Cranes, as a result of an extensive experimental and mathematical investigation. They apply to hooks of capacities from 250 lbs. to 20,000 lbs. Each size of hook is made from some commercial size of round iron. The basis in each case is, therefore, the size of iron of which the hook is to be made, indicated by *A* in the diagram. The dimension *D* is arbitrarily assumed. The other dimensions, as given by the formulæ, are those which, while preserving a proper bearing-face on the interior of the hook for the ropes or chains which may be passed through it, give the greatest resistance to spreading and to ultimate rupture, which the amount of material in the original bar admits of. The symbol  $\Delta$  is used to indicate the nominal capacity of the hook in tons of 2000 lbs. The formulæ which determine the lines of the other parts of the hooks of the several sizes are as follows, the measurements being all expressed in inches:

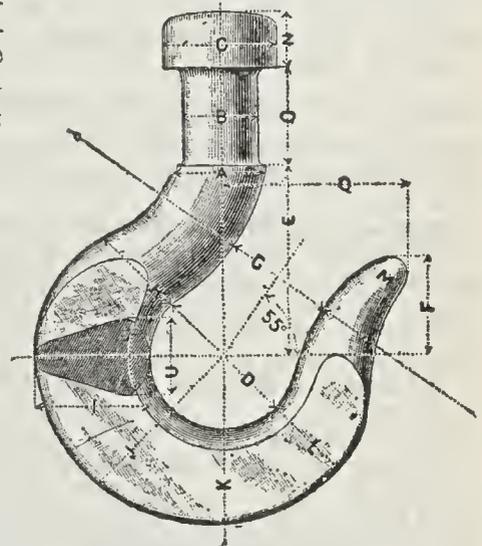

FIG. 164.

$$\begin{aligned}
 D &= .5 \Delta + 1.25 & G &= .75D. & H &= 1.08A & L &= 1.05A \\
 E &= .64 \Delta + 1.60 & O &= .363 \Delta + .66 & I &= 1.33A & M &= .50A \\
 F &= .33 \Delta + .85 & Q &= .64 \Delta + 1.60 & J &= 1.20A & N &= .85B - .16 \\
 & & & & K &= 1.13A & U &= .866A
 \end{aligned}$$

The dimensions *A* are necessarily based upon the ordinary merchant sizes of round iron. The sizes which it has been found best to select are the following:

Capacity of hook:												
$\frac{1}{8}$	$\frac{1}{4}$	$\frac{1}{2}$	1	1½	2	3	4	5	6	8	10 tons.	
Dimension <i>A</i> :												
$\frac{5}{8}$	$\frac{11}{16}$	$\frac{3}{4}$	$1 \frac{1}{16}$	$1 \frac{1}{4}$	$1 \frac{3}{8}$	$1 \frac{3}{4}$	2	$2 \frac{1}{4}$	$2 \frac{1}{2}$	$2 \frac{7}{8}$	$3 \frac{1}{4}$ in.	

Experiment has shown that hooks made according to the above formulæ will give way first by opening of the jaw, which, however, will not occur except with a load much in excess of the nominal capacity of the hook. This yielding of the hook when overloaded becomes a source of safety, as it constitutes a signal of danger which cannot easily be overlooked, and which must proceed to a considerable length before rupture will occur and the load be dropped.

### POWER OF HOISTING-ENGINES.

**Horse-power required to raise a Load at a Given Speed.** — H.P. =  $\frac{\text{Gross weight in lbs.}}{33,000} \times \text{speed in ft. per min.}$  To this add

25% to 50% for friction, contingencies, etc. The gross weight includes the weight of cage, rope, etc. In a shaft with two cages balancing each other use the net load + weight of one rope, instead of the gross weight.

To find the load which a given pair of engines will start.—Let  $A$  = area of cylinder in square inches, or total area of both cylinders, if there are two;  $P$  = mean effective pressure in cylinder in lbs. per sq. in.;  $S$  = stroke of cylinder in inches;  $C$  = circumference of hoisting-drum in inches;  $L$  = load lifted by hoisting-rope in lbs.;  $F$  = friction, expressed as a diminution of the load. Then  $L = \frac{AP^2S}{C} - F$ .

An example in *Coll'y Engr.*, July, 1891, is a pair of hoisting-engines 24"  $\times$  40", drum 12 ft. diam., average steam-pressure in cylinder = 59.5 lbs.;  $A$  = 904.8;  $P$  = 59.5;  $S$  = 40;  $C$  = 452.4. Theoretical load, not allowing for friction,  $AP^2S \div C$  = 9589 lbs. The actual load that could just be lifted on trial was 7988 lbs., making friction loss  $F$  = 1601 lbs., or 20 + per cent of the actual load lifted, or 16 $\frac{2}{3}$ % of the theoretical load.

The above rule takes no account of the resistance due to inertia of the load, but for all ordinary cases in which the acceleration of speed of the cage is moderate, it is covered by the allowance for friction, etc. The resistance due to inertia is equal to the force required to give the load the velocity acquired in a given time, or, as shown in Mechanics, equal to the product of the mass by the acceleration, or  $R = \frac{WV}{gT}$ , in which  $R$  = resistance in lbs. due to inertia;  $W$  = weight of load in lbs.;  $V$  = maximum velocity in feet per second;  $T$  = time in seconds taken to acquire the velocity  $V$ ;  $g$  = 32.16.

**Effect of Slack Rope upon Strain in Hoisting.**—A series of tests with a dynamometer are published by the Trenton Iron Co., which show that a dangerous extra strain may be caused by a few inches of slack rope. In one case the cage and full tubs weighed 11,300 lbs.; the strain when the load was lifted gently was 11,525 lbs.; with 3 in. of slack chain it was 19,025 lbs., with 6 in. slack 25,750 lbs., and with 9 in. slack 27,950 lbs.

**Limit of Depth for Hoisting.**—Taking the weight of a cast-steel hoisting-rope of 1 $\frac{1}{8}$  inches diameter at 2 lbs. per running foot, and its breaking strength at 84,000 lbs., it should, theoretically, sustain itself until 42,000 feet long before breaking from its own weight. But taking the usual factor of safety of 7, then the safe working length of such a rope would be only 6000 feet. If a weight of 3 tons is now hung to the rope, which is equivalent to that of a cage of moderate capacity with its loaded cars, the maximum length at which such a rope could be used, with the factor of safety of 7, is 3000 feet, or

$$2x + 6000 = \frac{84,000}{7}; \quad \therefore x = 3000 \text{ feet.}$$

This limit may be greatly increased by using special steel rope of higher strength, by using a smaller factor of safety, and by using taper ropes. (See paper by H. A. Wheeler, *Trans. A. I. M. E.*, xix, 107.)

**Large Hoisting Records.**—At a colliery in North Derbyshire during the first week in June, 1890, 6309 tons were raised from a depth of 509 yards, the time of winding being from 7 a.m. to 3.30 p.m.

At two other Derbyshire pits, 170 and 140 yards in depth, the speed of winding and changing has been brought to such perfection that tubs are drawn and changed three times in one minute. (*Proc. Inst. M. E.*, 1890.)

At the Nottingham Colliery near Wilkesbarre, Pa., in Oct. 1891, 70,152 tons were shipped in 24.15 days, the average hoist per day being 1318 mine cars. The depth of hoist was 470 feet, and all coal came from one opening. The engines were fast motion, 22 × 48 inches, conical drums 4 feet 1 inch long, 7 feet diameter at small end and 9 feet at large end. (*Eng'g News*, Nov. 1891.)

**Pneumatic Hoisting.** (H. A. Wheeler, *Trans. A. I. M. E.*, xix, 107.)—A pneumatic hoist was installed in 1876 at Epinac, France, consisting of two continuous air-tight iron cylinders extending from the bottom to the top of the shaft. Within the cylinder moved a piston from which was hung the cage. It was operated by exhausting the air from above the piston, the lower side being open to the atmosphere. Its use was discontinued on account of the failure of the mine. Mr. Wheeler gives a description of the system, but criticises it as not being equal on the whole to hoisting by steel ropes.

Pneumatic hoisting-cylinders using compressed air have been used at blast-furnaces, the weighted piston counterbalancing the weight of the cage, and the two being connected by a wire rope passing over a pulley-sheave above the top of the cylinder. In the more modern furnaces steam-engine hoists are generally used.

**Counterbalancing of Winding-engines.** (H. W. Hughes, *Columbia Coll. Qly.*)—Engines running unbalanced are subject to enormous variations in the load; for let  $W$  = weight of cage and empty tubs, say 6270 lbs.;  $c$  = weight of coal, say 4480 lbs.;  $r$  = weight of hoisting rope, say 6000 lbs.;  $r'$  = weight of counterbalance rope hanging down pit, say 6000 lbs. The weight to be lifted will be:

If weight of rope is unbalanced.	If weight of rope is balanced.		
At beginning of lift: $W + c + r - W$ or 10,480 lbs.	$W + c + r - (W + r')$ ,	}	
At middle of lift: $W + c + \frac{r}{2} - (W + \frac{r}{2})$ or 4480 lbs.	$W + c + \frac{r}{2} + \frac{r'}{2} - (W + \frac{r}{2} + \frac{r'}{2})$ ,		or 4480 lbs.
At end of lift: $W + c - (W + r)$ or minus 1520 lbs.	$W + c + r' - (W + r)$ ,		

That counterbalancing materially affects the size of winding-engines is shown by a formula given by Mr. Robert Wilson, which is based on the fact that the greatest work a winding-engine has to do is to get a given mass into a certain velocity uniformly accelerated from rest, and to raise a load the distance passed over during the time this velocity is being obtained.

Let  $W$  = the weight to be set in motion: one cage, coal, number of empty tubs on cage, one winding rope from pit head-gear to bottom, and one rope from banking level to bottom.

$v$  = greatest velocity attained, uniformly accelerated from rest;

$g$  = gravity = 32.2;

$t$  = time in seconds during which  $v$  is obtained;

$L$  = unbalanced load on engine;

$R$  = ratio of diameter of drum and crank circles;

$P$  = average pressure of steam in cylinders;

$N$  = number of cylinders;

$S$  = space passed over by crank-pin during time  $t$ ;

$C = \frac{2}{3}$ , constant to reduce angular space passed through by crank, to the distance passed through by the piston during the time  $t$ ;

$A$  = area of one cylinder, without margin for friction. To this an addition for friction, etc., of engine is to be made, varying from 10 to 30% of  $A$ .

1st. Where load is balanced,

$$A = \frac{\left\{ \left( \frac{Wv^2}{2g} \right) + \left( L \frac{vt}{2} \right) \right\} R}{PNSC.}$$

2d. Where load is unbalanced:

The formula is the same, with the addition of another term to allow for the variation in the lengths of the ascending and descending ropes. In this case

$h_1$  = reduced length of rope in  $t$  attached to ascending cage;  
 $h_2$  = increased length of rope in  $t$  attached to descending cage;  
 $w$  = weight of rope per foot in pounds. Then

$$A = \left[ \left( \frac{Wv^2}{2g} \right) + \left\{ \left( \frac{vt}{L^2} \right) - \frac{h_1w + h_2w}{2} \right\} \right] R$$

PNSC.

Applying the above formula when designing new engines, Mr. Wilson found that 30 inches diameter of cylinders would produce equal results, when balanced, to those of the 36-inch cylinder in use, the latter being unbalanced.

Counterbalancing may be employed in the following methods :

(a) *Tapering Rope*.—At the initial stage the tapering rope enables us to wind from greater depths than is possible with ropes of uniform section. The thickness of such a rope at any point should only be such as to safely bear the load on it at that point.

With tapering ropes we obtain a smaller difference between the initial and final load, but the difference is still considerable, and for perfect equalization of the load we must rely on some other resource. The theory of taper ropes is to obtain a rope of uniform strength, thinner at the cage end where the weight is least, and thicker at the drum end where it is greatest.

(b) *The Counterpoise System* consists of a heavy chain working up and down a staple pit, the motion being obtained by means of a special small drum placed on the same axis as the winding drum. It is so arranged that the chain hangs in full length down the staple pit at the commencement of the winding; in the centre of the run the whole of the chain rests on the bottom of the pit, and, finally, at the end of the winding the counterpoise has been rewound upon the small drum, and is in the same condition as it was at the commencement.

(c) *Loaded-wagon System*.—A plan, formerly much employed, was to have a loaded wagon running on a short incline in place of this heavy chain; the rope actuating this wagon being connected in the same manner as the above to a subsidiary drum. The incline was constructed steep at the commencement, the inclination gradually decreasing to nothing. At the beginning of a wind the wagon was at the top of the incline, and during a portion of the run gradually passed down it till, at the meet of cages, no pull was exerted on the engine—the wagon by this time being at the bottom. In the latter part of the wind the resistance was all against the engine, owing to its having to pull the wagon up the incline, and this resistance increased from nothing at the meet of cages to its greatest quantity at the conclusion of the lift.

(d) *The Endless-rope System* is preferable to all others, if there is sufficient sump room and the shaft is free from tubes, cross timbers, and other impediments. It consists in placing beneath the cages a tail rope, similar in diameter to the winding rope, and, after conveying this down the pit, it is attached beneath the other cage.

(e) *Flat Ropes Coiling on Reels*.—This means of winding allows of a certain equalization, for the radius of the coil of ascending rope continues to increase, while that of the descending one continues to diminish. Consequently, as the resistance decreases in the ascending load the leverage increases, and as the power increases in the other, the leverage diminishes. The variation in the leverage is a constant quantity, and is equal to the thickness of the rope where it is wound on the drum.

By the above means a remarkable uniformity in the load may be obtained, the only objection being the use of flat ropes, which weigh heavier and only last about two thirds the time of round ones.

(f) *Conical Drums*.—Results analogous to the preceding may be obtained by using round ropes coiling on conical drums, which may either be smooth, with the successive coils lying side by side, or they may be provided with a spiral groove. The objection to these forms is, that perfect equalization is not obtained with the conical drums unless the sides are very steep, and consequently there is great risk of the rope slipping; to obviate this, scroll drums were proposed. They are, however, very expensive, and the lateral displacement of the winding rope from the centre line of pulley becomes very great, owing to their necessary large width.

(g) *The Koepe System of Winding*.—An iron pulley with a single circular groove takes the place of the ordinary drum. The winding rope passes from one cage, over its head-gear pulley, round the drum, and, after pass

ing over the other head-gear pulley, is connected with the second cage. The winding rope thus encircles about half the periphery of the drum in the same manner as a driving-belt on an ordinary pulley. There is a balance rope beneath the cages, passing round a pulley in the sump; the arrangement may be likened to an endless rope, the two cages being simply points of attachment.

## CRANES.

**Classification of Cranes.** (Henry R. Towne, Trans. A. S. M. E., iv. 288. Revised in *Hoisting*, published by The Yale & Towne Mfg. Co.)

A Hoist is a machine for raising and lowering weights. A Crane is a hoist with the added capacity of moving the load in a horizontal or lateral direction.

Cranes are divided into two classes, as to their motions, viz., *Rotary* and *Rectilinear*, and into four groups, as to their source of motive power, viz.:

*Hand.*—When operated by manual power.

*Power.*—When driven by power derived from line shafting.

*Steam, Electric, Hydraulic, or Pneumatic.*—When driven by an engine or motor attached to the crane, and operated by steam, electricity, water, or air transmitted to the crane from a fixed source of supply.

*Locomotive.*—When the crane is provided with its own boiler or other generator of power, and is self-propelling; usually being capable of both rotary and rectilinear motions.

Rotary and Rectilinear Cranes are thus subdivided:

### ROTARY CRANES.

- (1) *Swing-cranes.*—Having rotation, but no trolley motion.
- (2) *Jib-cranes.*—Having rotation, and a trolley travelling on the jib.
- (3) *Column-cranes.*—Identical with the jib-cranes, but rotating around a fixed column (which usually supports a floor above).
- (4) *Pillar-cranes.*—Having rotation only; the pillar or column being supported entirely from the foundation.
- (5) *Pillar Jib-cranes.*—Identical with the last, except in having a jib and trolley motion.
- (6) *Derrick-cranes.*—Identical with jib-cranes, except that the head of the mast is held in position by guy-rods, instead of by attachment to a roof or ceiling.
- (7) *Walking-cranes.*—Consisting of a pillar or jib-crane mounted on wheels and arranged to travel longitudinally upon one or more rails.
- (8) *Locomotive-cranes.*—Consisting of a pillar crane mounted on a truck, and provided with a steam-engine capable of propelling and rotating the crane, and of hoisting and lowering the load.

### RECTILINEAR CRANES.

- (9) *Bridge-cranes.*—Having a fixed bridge spanning an opening, and a trolley moving across the bridge.
  - (10) *Tram-cranes.*—Consisting of a truck, or short bridge, travelling longitudinally on overhead rails, and without trolley motion.
  - (11) *Travelling-cranes.*—Consisting of a bridge moving longitudinally on overhead tracks, and a trolley moving transversely on the bridge.
  - (12) *Gantries.*—Consisting of an overhead bridge, carried at each end by a trestle travelling on longitudinal tracks on the ground, and having a trolley moving transversely on the bridge.
  - (13) *Rotary Bridge-cranes.*—Combining rotary and rectilinear movements and consisting of a bridge pivoted at one end to a central pier or post, and supported at the other end on a circular track; provided with a trolley moving transversely on the bridge.
- For descriptions of these several forms of cranes see Towne's "Treatise on Cranes."

**Stresses in Cranes.**—See Stresses in Framed Structures, p. 440, *ante*.

**Position of the Inclined Brace in a Jib-crane.**—The most economical arrangement is that in which the inclined brace intersects the jib at a distance from the mast equal to four fifths the effective radius of the crane. (*Hoisting*.)

**A Large Travelling-crane,** designed and built by the Morgan Engineering Co., Alliance, O., for the 12-inch-gun shop at the Washington Navy Yard, is described in *American Machinist*, June 12, 1890. Capacity, 150 net tons; distance between centres of inside rails, 59 ft. 6 in.; maximum cross travel, 44 ft. 2 in.; effective lift, 40 ft.; four speeds for main hoist, 1, 2.

4, and 8 ft. per min.; loads for these speeds, 150, 75,  $37\frac{1}{2}$ , and  $18\frac{3}{4}$  tons respectively; traversing speeds of trolley on bridge, 25 and 50 ft. per minute; speeds of bridge on main track, 30 and 60 ft. per minute. Square shafts are employed for driving.

**A 150-ton Pillar-crane** was erected in 1893 on Finnieston Quay, Glasgow. The jib is formed of two steel tubes, each 39 in. diam. and 90 ft. long. The radius of sweep for heavy lifts is 65 ft. The jib and its load are counterbalanced by a balance-box weighted with 100 tons of iron and steel punchings. In a test a 130-ton load was lifted at the rate of 4 ft. per minute, and a complete revolution made with this load in 5 minutes. *Eng'g News*, July 20, 1893.

**Compressed-air Travelling-cranes.**—Compressed-air overhead travelling-cranes have been built by the Lane & Bodley Co., of Cincinnati. They are of 20 tons nominal capacity, each about 50 ft. span and 400 ft. length of travel, and are of the triple-motor type, a pair of simple reversing-engines being used for each of the necessary operations, the pair of engines for the bridge and the pair for the trolley travel being each 5-inch bore by 7-inch stroke, while the pair for hoisting is 7-inch bore by 9-inch stroke. Air is furnished by a compressor having steam and air cylinders each 10-in. diam. and 12-in. stroke, which with a boiler-pressure of about 80 pounds gives an air-pressure when required of somewhat over 100 pounds. The air-compressor is allowed to run continuously without a governor, the speed being regulated by the resistance of the air in a receiver. From a pipe extending from the receiver along one of the supporting trusses communication is continuously maintained with an auxiliary receiver on each traveller by means of a one-inch hose, the object of the auxiliary receiver being to provide a supply of air near the engines for immediate demands and independent of the hose connection, which may thus be of small dimension. Some of the advantages said to be possessed by this type of crane are: simplicity; absence of all moving parts, excepting those required for a particular motion when that motion is in use; no danger from fire, leakage, electric shocks, or freezing; ease of repair; variable speeds and reversal without gearing; almost entire absence of noise; and moderate cost.

**Quay-cranes.**—An illustrated description of several varieties of stationary and travelling cranes, with results of experiments, is given in a paper on Quay-cranes in the Port of Hamburg by Chas. Nehls, Trans. A. S. C. E., Chicago Meeting, 1893.

**Hydraulic Cranes, Accumulators, etc.**—See Hydraulic Pressure Transmission, page 616, *ante*.

**Electric Cranes.**—Travelling-cranes driven by electric motors have largely supplanted cranes driven by square shafts or flying-ropes. Each of the three motions, viz., longitudinal, traversing and hoisting, is usually accomplished by a separate motor carried upon the crane.

## COAL-HANDLING MACHINERY.

The following notes and tables are supplied by the Link-Belt Engineering Co. of Philadelphia, Pa.:

In large boiler-houses coal is usually delivered from hopper-cars into a track-hopper, about 10 feet wide, and 12 to 16 feet long. A feeder set under the track-hopper feeds the coal at a regular rate to a crusher, which reduces it to a size suitable for stokers.

After crushing, the coal is elevated or conveyed to overhead storage-bins. Overhead storage is preferred for several reasons:

1. To avoid expensive wheeling of coal in case of a breakdown of the coal-handling machinery.
2. To avoid running the coal-handling machinery continuously.
3. Coal kept under cover indoors will not freeze in winter and clog the supply-spouts to the boilers.
4. It is often cheaper to store overhead than to use valuable ground-space adjacent to the boiler-house.
5. As distinguished from vault or outside hopper storage, it is cheaper to build steel bins and supports than masonry pits.

**Weight of Overhead Bins.**—Steel bins of approximately rectangular cross-section, say 10×10 feet, will weigh, exclusive of supports, about one-sixth as much as the contained coal. Larger bins, with sloping bottoms, may weigh one-eighth as much as the contained coal. Bag bottom bins of the Berquist type will weigh about one-twelfth as much as the contained coal, not including posts, and about one-ninth as much, including posts.

**Supply-pipes from Bins.**—The supply-pipes from overhead bins to the boiler-room floor, or to the stoker-hoppers, should not be less than 12 inches in diameter. They should be fitted at the top with a flanged casting and a cut-off gate, to permit removal of the pipe when the boilers are to be cleaned or repaired.

**Types of Coal Elevators.**—Coal elevators consist of buckets of various shapes attached to one or more strands of link-belt or chain, or to rubber belting. The buckets may either be attached continuously or at intervals. The various types are as follows:

*Continuous bucket elevators* consist usually of one strand of chain and two sprocket-wheels with buckets attached continuously to the chain. Each bucket after passing the head wheel acts as a chute to direct the flow from the next bucket. This type of elevator will handle the larger sizes of coal. It runs at slow speeds, usually from 90 to 175 feet per minute, and has a maximum capacity of about 120 tons per hour.

*Centrifugal discharge elevators* consist usually of a single strand of chain, with the buckets attached thereto at intervals. They are used to handle the smaller sizes of coal in small quantities. They run at high speeds, usually 34 to 40 revolutions of the head wheel per minute, and have a capacity up to 40 tons per hour.

*Perfect discharge elevators* consist of two strands of chain, with buckets at intervals between them. A pair of idlers set under the head wheels cause the buckets to be completely inverted, and to make a clean delivery into the chutes at the elevator head. This type of elevator is useful in handling material which tends to cling to the buckets. It runs at slow speeds, usually less than 150 feet per minute. The capacity depends on the size of the buckets.

**Combined Elevators and Conveyors** are of the following types:

*Gravity discharge elevators*, consisting of two strands of chain, with spaced V-shaped buckets fastened between them. After passing the head wheels the buckets act as conveyor-flights and convey the coal in a trough to any desired point. This is the cheapest type of combined elevator and conveyor, and is economical of power. A machine carrying 100 tons of coal per hour, in buckets 20 inches wide, 10 inches deep, and 24 inches long, spaced 3 feet apart, requires 5 H.P. when loaded and 1½ H.P. when empty for each 100 feet of horizontal run, and ¼ H.P. for each foot of vertical lift.

*Rigid bucket-carriers* consist of two strands of chain with a special bucket rigidly fastened between them. The buckets overlap and are so shaped that they will carry coal around three sides of a rectangle. The coal is carried to any desired point and is discharged by completely inverting the bucket over a turn-wheel.

*Pivoted bucket-carriers* consist of two strands of long pitch steel chain to which are attached, in a pivotal manner, large malleable iron or steel buckets so arranged that their adjacent lips are close together or overlap. Overlapping buckets require special devices for changing the lap at the corner turns. Carriers in which the buckets do not overlap should be fitted with auxiliary pans or buckets, arranged in such a manner as to catch the spill which falls between the lips at the loading point, and so shaped as to return the spill to the buckets at the corner turns. Pivoted bucket carriers will carry coal around four sides of a rectangle, the buckets being dumped on the horizontal run by striking a cam suitably placed. Carriers of this type are economical of power, but are costly and of relatively low capacity.

**Coal Conveyors.**—Coal conveyors are of four general types, viz., scraper or flight, bucket, screw, and belt conveyors.

*The flight conveyor* consists of a trough of any desired cross-section and a single or double strand of chain carrying scrapers or flights of approximately the same shape as the trough. The flights push the coal ahead of them in the trough to any desired point, where it is discharged through openings in the bottom of the trough.

For short, low-capacity conveyors, malleable link hook-joint chains are used. For heavier service, malleable pin-joint chains, steel link chains,

or monobar, are required For the heaviest service, two strands of steel link chain, usually with rollers, are used.

Flight conveyors are of three types: plain scraper, suspended flight, and roller flight

In the plain scraper conveyor, the flight is suspended from the chain and drags along the bottom of the trough. It is of low first cost and is useful where noise of operation is not objectionable. It has a maximum capacity of about 30 tons per hour, and requires more power than either of the other two types of flight conveyors.

*Suspended flight conveyors* use one or two strands of chain. The flights are attached to cross-bars having wearing-shoes at each end. These wearing-shoes slide on angle-iron tracks on each side of the conveyor trough. The flights do not touch the trough at any point. This type of conveyor is used where quietness of operation is a consideration. It is of higher first cost than the plain scraper conveyor, but requires one-fourth less power for operation. It is economical up to a capacity of about 80 tons per hour.

*The roller flight conveyor* is similar to the suspended flight, except that the wearing-shoes are replaced by rollers. It is highest in first cost of all the flight conveyors, but has the advantages of low power consumption (one-half that of the scraper), low stress in chain, long life of chain, trough, and flights, and noiseless operation. It has an economical maximum capacity of about 120 tons per hour.

The following formula gives approximately the horse-power at the head wheel required to operate flight conveyors:

$$H.P. = (ATL + BWS) \div 1000.$$

*T*=tons of coal per hour; *L*=length of conveyor in feet, centre to centre; *W*=weight of chain, flights, and shoes (both runs) in pounds; *S*=speed in feet per minute; *A* and *B* constants depending on angle of incline from horizontal. See example below.

**Values of A and B.**

Angle, Deg.	A	B	Angle, Deg.	A	B	Angle, Deg.	A	B
0	.343	.01	10	.50	.01	30	.79	.009
2	.378	.01	14	.57	.01	34	.84	.008
4	.40	.01	18	.63	.009	38	.88	.008
6	.44	.01	22	.69	.009	42	.92	.007
8	.47	.01	26	.74	.009	46	.95	.007

For suspended flight conveyors take *B* as 0.8, and for roller flights as 0.6, of the values given in the table.

**Weight of Chain in Pounds per Foot.**

LINK-BELTING.					MONOBAR.							
Chain No.	Pitch of Flights, Inches.				Chain No.*	Pitch of Flights, Inches.						
	12	18	24	36		12	18	24	36	48	54	72
78	2.4	2.3	2.26	2.2	612	3.9	.....	3.6	3.5	.....	.....	.....
88	2.8	2.7	2.6	2.5	618	.....	3.0	.....	2.8	.....	2.7	.....

\* In monobar the first one or two figures in the number of the chain denote the diameter of the chain in eighths of an inch. The last two figures denote the pitch in inches.

PIN CHAINS.					ROLLER CHAINS.							
No.	Pitch of Flights, Inches.				No.	Pitch of Flights, Inches.						
	12	18	24	36		12	18	24	36			
720	5.9	5.6	5.4	5.3	1112	7.7	6.9	6.2	5.7			
730	6.9	6.6	6.4	6.3	1113	9.5	8.8	8.0	7.5			
825	9.6	9.3	9.1	8.9	1130	10.5	9.5	9.0	7.8			

**Weight of Flights with Wearing-shoes and Bolts.**

Size, Inches.	Steel.	Malleable Iron.	Suspended Flights.	
			Size.	Weight, Lbs.
4×10	3.5	4.3	6×14	12.37
4×12	3.9	4.7	8×19	15.55
5×10	4.1	5.2	10×24	25.57
5×12	4.6	5.7	10×30	29.37
5×15	5.8	5.9	10×36	33.17
6×18	8.1	9.2	10×42	34.97
8×18	10.1	12.7		
8×20	11.0	13.4		
8×24	12.6	14.4		
10×24	15.2	17.4		

EXAMPLE.—Required the H.P. for a monobar conveyor 200 ft. centre to centre, carrying 100 tons of coal per hour, up a 10° incline at a speed of 100 feet per minute. Conveyor has No. 818 chain and 8×19 suspended flights, spaced 18 inches apart.

$$\text{H.P.} = \frac{.5 \times 100 \times 200 + .008(400 \times 5.7 + 267 \times 15.55) \times 100}{1000} = 15.15.$$

The following table shows the conveying capacities of various sizes of flights at 100 feet per minute in tons of 2000 lbs. per hour. The values are true for continuous feed only.

Size of Flight.	Horizontal Conveyors.				Inclined Conveyors.		
	Flight Every 16".	Flight Every 18".	Flight Every 24".	Pounds Coal per Flight.	10° Flights Every 24".	20° Flights Every 24".	30° Flights Every 24".
	Tons.	Tons.	Tons.		Tons.	Tons.	Tons.
6×14	69.75	62	46.5	31	40.5	31.5	22.5
8×19	.....	130	97.5	65	78	62	52
10×24	.....	.....	172.5	115	150	120	90
10×30	.....	.....	220	147	184	146	116
10×36	.....	.....	268	179	225	177	142
10×42	.....	.....	315	210	264	210	167

**Bucket Conveyors.**—Rigid bucket-carriers are used to convey large quantities of coal over a considerable distance when there is no intermediate point of discharge. These conveyors are made with two strands of steel roller chain. They are built to carry as much as 10 tons of coal per minute.

**Screw Conveyors.**—Screw conveyors consist of a helical steel flight, either in one piece or in sections, mounted on a pipe or shaft, and running in a steel or wooden trough. These conveyors are made from 4 to 18 inches in diameter, and in sections 8 to 12 feet long. The speed ranges from 20 to 60 revolutions per minute and the capacity from 10 to 30 tons of coal per hour. It is not advisable to use this type of conveyor for coal, as it will only handle the smaller sizes and the flights are very easily damaged by any foreign substance of unusual size or shape.

**Belt Conveyors.**—Rubber or cotton belt conveyors are used for handling coal, grain, sand, or other finely divided material. They combine a high carrying capacity with low power consumption, but are relatively high in first cost.

In some cases the belt is flat, the material being fed to the belt at its centre in a narrow stream. In the majority of cases, however, the belt is troughed by means of idler pulleys set at an angle from the horizontal and placed at intervals along the length of the belt. Rubber belts are very often made more flexible for deep troughing by removing some of the layers of cotton from the belt and substituting therefor an extra thickness of rubber.

Belt conveyors may be used for elevating materials up to about 23° incline. On greater inclines the material slides back on the belt and spills. With many substances it is important to feed the belt steadily if the conveyor stands at or near the limiting angle. If the flow is interrupted the material may slide back on the belt.

Belt conveyors are run at any speed from 200 to 800 feet per minute, and are made in widths varying from 12 inches to 60 inches.

#### Capacity of Belt Conveyors in Tons of Coal per Hour.

Width of Belt, Ins.	Velocity of Belt, Feet per Minute.						
	300	350	400	450	500	550	600
12	27	31.5	36	40.5	45	49.5	54
14	36.7	42.8	49	55.2	61.3	67.4	73.6
16	48	56	64	72	80	88	96
18	60.7	70.8	81	91.2	101	111	135
20	75	87.5	100	112.5	125	137.5	150
24	108	126	144	162	180	198	216
30	168.7	197	225	253	281	307	338
36	243	283	324	365	405	446	486

For materials other than coal, the figures in the above table should be multiplied by the coefficients given in the table below:

Material.	Coefficient.	Material.	Coefficient.
Ashes (damp).....	0.86	Earth.....	1.4
Cement.....	1.76	Sand.....	1.8
Clay.....	1.26	Stone (crushed).....	2.0
Coke.....	0.60		

**Carrying-bands or Belts,** used for the purpose of sorting coal and removing impurities, are sometimes made of an endless length of woven wire, or of two or three endless chains, carrying steel plates varying in width from 6 inches to 14 inches. (Proc. Inst. M. E., July, 1890.)

**Grain-elevators.**—American Grain-elevators are described in a paper by E. Lee Heidenreich, read at the International Engineering Congress at Chicago (Trans. A. S. C. E., 1893). See also Trans. A. S. M. E., vii, 660.

#### WIRE-ROPE HAULAGE.

Methods for transporting coal and other products by means of wire rope, though varying from each other in detail, may be grouped in five classes:

- I. The Self-acting or Gravity Inclined Plane.
- II. The Simple Engine-plane.

- III. The Tail-rope System.
- IV. The Endless-rope System
- V. The Cable Tramway.

The following brief description of these systems is abridged from a pamphlet on Wire-rope Haulage, by Wm. Hildenbrand, C.E., published by John A. Roebling's Sons Co., Trenton, N. J.

**I. The Self-acting Inclined Plane.**—The motive power for the self-acting inclined plane is gravity; consequently this mode of transporting coal finds application only in places where the coal is conveyed from a higher to a lower point and where the plane has sufficient grade for the loaded descending cars to raise the empty cars to an upper level.

At the head of the plane there is a drum, which is generally constructed of wood, having a diameter of seven to ten feet. It is placed high enough to allow men and cars to pass under it. Loaded cars coming from the pit are either singly or in sets of two or three switched on the track of the plane, and their speed in descending is regulated by a brake on the drum.

Supporting rollers, to prevent the rope dragging on the ground, are generally of wood, 5 to 6 inches in diameter and 18 to 24 inches long, with  $\frac{3}{4}$ - to  $\frac{7}{8}$ -inch iron axles. The distance between the rollers varies from 15 to 30 feet, steeper planes requiring less rollers than those with easy grades. Considering only the reduction of friction and what is best for the preservation of rope, a general rule may be given to use rollers of the greatest possible diameter, and to place them as close as economy will permit.

The smallest angle of inclination at which a plane can be made self-acting will be when the motive and resisting forces balance each other. The motive forces are the weights of the loaded car and of the descending rope. The resisting forces consist of the weight of the empty car and ascending rope, of the rolling and axle friction of the cars, and of the axle friction of the supporting rollers. The friction of the drum, stiffness of rope, and resistance of air may be neglected. A general rule cannot be given, because a change in the length of the plane or in the weight of the cars changes the proportion of the forces; also, because the coefficient of friction, depending on the condition of the road, construction of the cars, etc., is a very uncertain factor.

For working a plane with a  $\frac{5}{8}$ -inch steel rope and lowering from one to four pit cars weighing empty 1400 lbs. and loaded 4000 lbs., the rise in 100 feet necessary to make the plane self-acting will be from about 5 to 10 feet, decreasing as the number of cars increase, and increasing as the length of plane increases.

A gravity inclined plane should be slightly concave, steeper at the top than at the bottom. The maximum deflection of the curve should be at an inclination of 45 degrees, and diminish for smaller as well as for steeper inclinations.

**II. The Simple Engine-plane.**—The name "Engine-plane" is given to a plane on which a load is raised or lowered by means of a single wire rope and stationary steam-engine. It is a cheap and simple method of conveying coal underground, and therefore is applied wherever circumstances permit it.

Under ordinary conditions such as prevail in the Pennsylvania mine region, a train of twenty-five to thirty loaded cars will descend, with reasonable velocity, a straight plane 5000 feet long on a grade of  $1\frac{3}{4}$  feet in 100, while it would appear that  $2\frac{1}{4}$  feet in 100 is necessary for the same number of empty cars. For roads longer than 5000 feet, or when containing sharp curves, the grade should be correspondingly larger.

**III. The Tail-rope System.**—Of all methods for conveying coal underground by wire rope, the tail-rope system has found the most application. It can be applied under almost any condition. The road may be straight or curved, level or undulating, in one continuous line or with side branches. In general principle a tail-rope plane is the same as an engine-plane worked in both directions with two ropes. One rope, called the "main rope," serves for drawing the set of full cars outward; the other, called the "tail-rope," is necessary to take back the empty set, which on a level or undulating road cannot return by gravity. The two drums may be located at the opposite ends of the road, and driven by separate engines, but more frequently they are on the same shaft at one end of the plane. In the first case each rope would require the length of the plane, but in the second case the tail rope must be twice as long, being led from the drum around a sheave at the other end of the plane and back again to its starting-

point. When the main rope draws a set of full cars out, the tail-rope drum runs loose on the shaft, and the rope, being attached to the rear car, unwinds itself steadily. Going in, the reverse takes place. Each drum is provided with a brake to check the speed of the train on a down grade and prevent its overrunning the forward rope. As a rule, the tail rope is strained less than the main rope, but in cases of heavy grades dipping outward it is possible that the strain in the former may become as large, or even larger, than in the latter, and in the selection of the sizes reference should be had to this circumstance.

**IV. The Endless-rope System.**—The principal features of this system are as follows:

1. The rope, as the name indicates, is endless.
2. Motion is given to the rope by a single wheel or drum, and friction is obtained either by a grip-wheel or by passing the rope several times around the wheel.
3. The rope must be kept constantly tight, the tension to be produced by artificial means. It is done in placing either the return-wheel or an extra tension wheel on a carriage and connecting it with a weight hanging over a pulley, or attaching it to a fixed post by a screw which occasionally can be shortened.
4. The cars are attached to the rope by a grip or clutch, which can take hold at any place and let go again, starting and stopping the train at will, without stopping the engine or the motion of the rope.
5. On a single-track road the rope works forward and backward, but on a double track it is possible to run it always in the same direction, the full cars going on one track and the empty cars on the other.

This method of conveying coal, as a rule, has not found as general an introduction as the tail-rope system, probably because its efficacy is not so apparent and the opposing difficulties require greater mechanical skill and more complicated appliances. Its advantages are, first, that it requires one third less rope than the tail-rope system. This advantage, however, is partially counterbalanced by the circumstance that the extra tension in the rope requires a heavier size to move the same load than when a main and tail rope are used. The second and principal advantage is that it is possible to start and stop trains at will without signalling to the engineer. On the other hand, it is more difficult to work curves with the endless system, and still more so to work different branches, and the constant stretch of the rope under tension or its elongation under changes of temperature frequently causes the rope to slip on the wheel, in spite of every attention, causing delay in the transportation and injury to the rope.

**V. Wire-rope Tramways.**—The methods of conveying products on a suspended rope tramway find especial application in places where a mine is located on one side of a river or deep ravine and the loading station on the other. A wire rope suspended between the two stations forms the track on which material in properly constructed "carriages" or "buggies" is transported. It saves the construction of a bridge or trestlework, and is practical for a distance of 2000 feet without an intermediate support.

There are two distinct classes of rope tramways:

1. The rope is stationary, forming the track on which a bucket holding the material moves forward and backward, pulled by a smaller endless wire rope.
2. The rope is movable, forming itself an endless line, which serves at the same time as supporting track and as pulling rope.

Of these two the first method has found more general application, and is especially adapted for long spans, steep inclinations, and heavy loads. The second method is used for long distances, divided into short spans, and is only applicable for light loads which are to be delivered at regular intervals.

For detailed descriptions of the several systems of wire-rope transportation, see circulars of John A. Roebling's Sons Co., The Trenton Iron Co., and other wire-rope manufacturers. See also paper on Two-rope Haulage Systems, by R. Van A. Norris, *Trans. A. S. M. E.*, xii, 626.

*In the Bleichert System* of wire-rope tramways, in which the track rope is stationary, loads of 1000 pounds each and upward are carried. While the average spans on a level are from 150 to 200 feet, in crossing rivers, ravines, etc., spans up to 1500 feet are frequently adopted. In a tramway on this system at Granite, Montana, the total length of the line is 9750 feet, with a fall of 1225 feet. The descending loads, amounting to a constant weight of about 11 tons, develop over 14 horse-power, which is sufficient to haul the empty buckets as well as about 50 tons of supplies per day up the line, and

also to run the ore crusher and elevator. It is capable of delivering 250 tons of material in 10 hours.

**Suspension Cableways or Cable Hoist-conveyors.**

(Trenton Iron Co.)

In quarrying, rock-cutting, stripping, piling, dam-building, and many other operations where it is necessary to hoist and convey large individual loads economically, it frequently happens that the application of a system of derricks is impracticable, by reason of the limited area of their efficiency and the room which they occupy.

To meet such conditions cable hoist-conveyors are adapted, as they can be operated in clear spans up to 1500 feet, and in lifting individual loads up to 15 tons. Two types are made—one in which the hoisting and conveying are done by separate running ropes, and the other applicable only to inclines, in which the carriage descends by gravity, and but one running rope is required. The moving of the carriage in the former is effected by means of an endless rope, and these are commonly known as "endless-rope" hoist-conveyors to distinguish them from the latter, which are termed "inclined" hoist-conveyors.

The general arrangement of the endless-rope hoist-conveyors consists of a main cable passing over towers, A frames or masts, as may be most convenient, and anchored firmly to the ground at each end, the requisite tension in the cable being maintained by a turnbuckle at one anchorage.

Upon this cable travels the carriage, which is moved back and forth over the line by means of the endless rope. The hoisting is done by a separate rope, both ropes being operated by an engine specially designed for the purpose, which may be located at either end of the line, and is constructed in such a way that the hoisting-rope is coiled up or paid out automatically as the carriage is moved in and out. Loads may be picked up or discharged at any point along the line. Where sufficient inclination can be obtained in the main cable for the carriage to descend by gravity, and the loading and unloading is done at fixed points, the endless rope can be dispensed with. The carriage, which is similar in construction to the carriage used in the endless-rope cableways, is arrested in its descent by a stop-block, which may be clamped to the main cable at any desired point, the speed of the descending carriage being under control of a brake on the engine-drum.

**Stress in Hoisting-ropes on Inclined Planes.**

(Trenton Iron Co.)

Rise per 100 ft. horizontal.	Angle of inclination.	Stress in lbs. per ton of 2000 lbs.	Rise per 100 ft. horizontal.	Angle of inclination.	Stress in lbs. per ton of 2000 lbs.	Rise per 100 ft. horizontal.	Angle of inclination.	Stress in lbs. per ton of 2000 lbs.
ft.			ft.			ft.		
5	2° 52'	140	55	28° 49'	1003	110	47° 44'	1516
10	5° 43'	240	60	30° 58'	1067	120	50° 12'	1573
15	8° 32'	336	65	33° 02'	1128	130	52° 26'	1620
20	11° 10'	432	70	35° 00'	1185	140	54° 28'	1663
25	14° 03'	527	75	36° 53'	1238	150	56° 19'	1699
30	16° 42'	613	80	38° 40'	1287	160	58° 00'	1730
35	19° 18'	700	85	40° 22'	1332	170	59° 33'	1758
40	21° 49'	782	90	42° 00'	1375	180	60° 57'	1782
45	24° 14'	860	95	43° 32'	1415	190	62° 15'	1804
50	26° 34'	933	100	45° 00'	1450	200	63° 27'	1822

The above table is based on an allowance of 40 lbs. per ton for rolling friction, but an additional allowance must be made for stress due to the weight of the rope proportional to the length of the plane. A factor of safety of 5 to 7 should be taken.

In hoisting the slack-rope should be taken up gently before beginning the lift, otherwise a severe extra strain will be brought on the rope.

A *Double-suspension Cableway*, carrying loads of 15 tons, erected near Williamsport, Pa., by the Trenton Iron Co., is described by E. G. Spilsbury in *Trans. A. I. M. E.* xx. 766. The span is 733 feet, crossing the Susquehanna River. Two steel cables, each 2 in. diam., are used. On these cables runs a carriage supported on four wheels and moved by an endless cable 1 inch in diam. The load consists of a cage carrying a railroad-car loaded with lum-

ber. the latter weighing about 12 tons. The power is furnished by a 50-H.P. engine, and the trip across the river is made in about three minutes.

A hoisting cableway on the endless-rope system, erected by the Lidgerwood Mfg. Co., at the Austin Dam, Texas, had a single span 1350 ft. in length, with main cable  $2\frac{1}{2}$  in. diam., and hoisting-rope  $1\frac{3}{4}$  in. diam. Loads of 7 to 8 tons were hauled at a speed of 600 to 800 ft. per minute.

Another, of still longer span, 1650 ft., was erected by the same company at Holyoke, Mass., for use in the construction of a dam. The main cable is the Elliott or locked wire cable, having a smooth exterior. In the construction of the Chicago Drainage Canal twenty cableways, of 700 ft. span and 8 tons capacity, were used, the towers travelling on rails.

**Tension required to Prevent Slipping of Rope on Drum.** (Trenton Iron Co.)—The amount of artificial tension to be applied in an endless rope to prevent slipping on the driving-drum depends on the character of the drum, the condition of the rope and number of laps which it makes. If  $T$  and  $S$  represent respectively the tensions in the taut and slack lines of the rope;  $W$ , the necessary weight to be applied to the tail-sheave;  $R$ , the resistance of the cars and rope, allowing for friction;  $n$ , the number of half-laps of the rope on the driving-drum; and  $f$ , the coefficient of friction, the following relations must exist to prevent slipping:

$$T = Se^{fn\pi}, \quad W = T + S, \quad \text{and} \quad R = T - S;$$

from which we obtain 
$$W = \frac{e^{fn\pi} + 1}{e^{fn\pi} - 1} R,$$

in which  $e = 2.71828$ , the base of the Napierian system of logarithms.

The following are some of the values of  $f$ :

	Dry.	Wet.	Greasy.
Wire-rope on a grooved iron drum.....	.120	.085	.070
Wire-rope on wood-filled sheaves....	.235	.170	.140
Wire-rope on rubber and leather filling..	.495	.400	.205

The importance of keeping the rope dry is evident from these figures.

The values of the coefficient  $\frac{e^{fn\pi} + 1}{e^{fn\pi} - 1}$ , corresponding to the above values

of  $f$ , for one up to six half-laps of the rope on the driving-drum or sheaves, are as follows:

$f$	$n = \text{Number of Half-laps on Driving-wheel.}$					
	1	2	3	4	5	6
.070	9.130	4.623	3.111	2.418	1.999	1.729
.085	7.536	3.893	2.629	2.047	1.714	1.505
.120	5.345	2.777	1.953	1.570	1.358	1.232
.140	4.623	2.418	1.729	1.416	1.249	1.154
.170	3.833	2.047	1.505	1.263	1.149	1.085
.205	3.212	1.762	1.338	1.165	1.083	1.043
.235	2.831	1.592	1.245	1.110	1.051	1.024
.400	1.795	1.176	1.047	1.013	1.004	1.001
.495	1.538	1.093	1.019	1.004	1.001	.....

When the rope is at rest the tension is distributed equally on the two lines of the rope, but when running there will be a difference in the tensions of the taut and slack lines equal to the resistance, and the values of  $T$  and  $S$  may be readily computed from the foregoing formulæ.

**Taper Ropes of Uniform Tensile Strength.**—The true form of rope is not a regular taper but follows a logarithmic curve, the girth rapidly increasing toward the upper end. Mr. Chas. D. West gives the following formula, based on a breaking strain of 80,000 lbs. per sq. in. of the rope, core included, and a factor of safety of 10:  $\log G = F/3680 + \log g$ , in which  $F =$  length in fathoms, and  $G$  and  $g$  the girth in inches at any two sections  $F$  fathoms apart. The girth  $g$  is first calculated for a safe strain of 8000 lbs. per sq. in., and then  $G$  is obtained by the formula. For a mathematical investigation see *The Engineer*, April, 1880, p. 267.

## TRANSMISSION OF POWER BY WIRE ROPE.

The following notes have been furnished to the author by Mr. Wm Hewitt, Vice-President of the Trenton Iron Co. (See also circulars of the Trenton Iron Co. and of the John A. Roebling's Sons Co., Trenton, N. J.: "Transmission of Power by Wire Ropes," by A. W. Stahl, Van Nostrand's Science Series, No. 28; and Reuleaux's Constructor.)

The force transmitted should not exceed the difference between the elastic limit of the wires and the bending stress as determined by the following tables, taking the elastic limit of tempered steel, such as is used in the best rope, at 57,000 lbs. per sq. in., and that of Swedish iron at half this, or 28,500 lbs. (The el. lim. of fine steel wires may be higher than 57,000 lbs.)

### Elastic Limit of Wire Ropes.

7/8	.058	.301198		
1	.067	.401925		

The elastic limit of 19-wire rope may be taken the same as for 7-wire rope since the ultimate strength of the wires is 7 to 10 per cent greater.

The working tension may be greater, therefore, as the bending stress is less; but since the tension in the slack portion of the rope cannot be less than a certain proportion of the tension in the taut portion, to avoid slipping, a ratio exists between the diameter of sheave and the wires composing the rope, corresponding to a maximum safe working tension. This ratio depends upon the number of laps that the rope makes about the sheaves, and the kind of filling in the rims, or the character of the material upon which the rope tracks.

**The sheaves** (Fig. 165) are usually of cast iron, and are made as light as possible consistent with the requisite strength. Various materials have been used for filling the bottom of the groove, such as tarred oakum, jute yarn, hard wood, India-rubber, and leather. The filling which gives the best satisfaction, however, in ordinary transmissions consists of segments of leather and blocks of India-rubber soaked in tar and packed alternately in the groove. Where the working tension is very

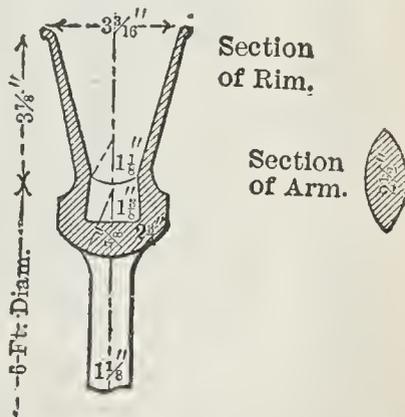

FIG. 165.

great, however, the wood filling is to be preferred, as in the case of long-distance transmissions where the rope makes several laps about the sheaves, and is run at a comparatively slow speed.

**The Bending Stress** is determined by the formula

$$k = \frac{Ea}{2.06(R + d) + C}$$

$k$  = bending stress in lbs.;  $E$  = modulus of elasticity = 28,500,000;  $a$  = aggregate area of wires, sq. ins.;  $R$  = radius of bend;  $d$  = diam. of wires, ins.

For 7-wire rope  $d = 1/9$  diam. of rope;  $C = 27.54$ .

“ 19-wire “  $d = 1/15$  “ “ “ ;  $C = 45.9$ .

From this formula the tables below have been calculated.

**Bending Stresses, 7-wire Rope.**

**Horse-Power Transmitted.**—The general formula for the amount of power capable of being transmitted is as follows:

$$\text{H.P.} = [cd^2 - .000006(w + g_1 + g_2)]v;$$

in which  $d$  = diameter of the rope in inches,  $v$  = velocity of the rope in feet per second,  $w$  = weight of the rope,  $g_1$  = weight of the terminal sheaves and shafts,  $g_2$  = weight of the intermediate sheaves and shafts (all in lbs.), and  $c$  = a constant depending on the material of the rope, the filling in the grooves of the sheaves, and the number of laps about the sheaves or drums, a single lap meaning a half-lap at each end. The values of  $c$  for one up to six laps for steel rope are given in the following table:

$c$ = for steel rope on	Number of Laps about Sheaves or Drums.					
	1	2	3	4	5	6
Iron.....	5.61	8.81	10.62	11.65	12.16	12.56
Wood.....	6.70	9.93	11.51	12.26	12.66	12.83
Rubber and leather.....	9.29	11.95	12.70	12.91	12.97	13.00

The values of  $c$  for iron rope are one half the above.

When more than three laps are made, the character of the surface in contact is immaterial as far as slippage is concerned.

From the above formula we have the general rule, that *the actual horse-power capable of being transmitted by any wire rope approximately equals  $c$  times the square of the diameter of the rope in inches, less six millionths the entire weight of all the moving parts, multiplied by the speed of the rope, in feet per second.*

Instead of grooved drums or a number of sheaves, about which the rope makes two or more laps, it is sometimes found more desirable, especially where space is limited, to use grip-pulleys. The rim is fitted with a continuous series of steel jaws, which bite the rope in contact by reason of the pressure of the same against them, but as soon as relieved of this pressure they open readily, offering no resistance to the egress of the rope.

In the ordinary or "flying" transmission of power, where the rope makes a single lap about sheaves lined with rubber and leather or wood, the ratio between the diameter of the sheaves and the wires of the rope, corresponding to a maximum safe working tension, is : For 7-wire rope, steel, 76.9; iron, 157.8. For 12-wire rope, steel, 59.3; iron, 122.6. For 19-wire rope, steel, 44.5; iron, 93.1.

### Diameters of Minimum Sheaves in Inches, Corresponding to a Maximum Safe Working Tension.

Diameter of Rope. In.	Steel.			Iron.		
	7-Wire.	12-Wire.	19-Wire.	7-Wire.	12-Wire.	19 Wire.
$\frac{1}{4}$	19	15	11	39	31	23
$\frac{5}{16}$	24	19	14	49	38	29
$\frac{3}{8}$	29	22	17	59	46	35
$\frac{7}{16}$	34	26	19	69	54	41
$\frac{1}{2}$	38	30	22	79	61	47
$\frac{9}{16}$	43	33	25	89	69	52
$\frac{5}{8}$	48	37	28	99	77	58
$\frac{11}{16}$	53	41	31	109	84	64
$\frac{3}{4}$	58	44	34	119	92	70
$\frac{7}{8}$	67	52	39	138	107	81
1	77	59	45	158	123	93

Assuming the sheaves to be of equal diameter, and of the sizes in the above table, the horse-power that may be transmitted by a steel rope making a single lap on wood-filled sheaves is given in the table on the next page.

The transmission of greater horse-powers than 250 is impracticable with filled sheaves, as the tension would be so great that the filling would quickly cut out, and the adhesion on a metallic surface would be insufficient where the rope makes but a single lap. In this case it becomes necessary to use the Renleaux method, in which the rope is given more than one lap, as referred to below, under the caption "Long-distance Transmissions."

### Horse-power Transmitted by a Steel Rope on Wood-filled Sheaves.

Diameter of Rope. In.	Velocity of Rope in Feet per Second.									
	10	20	30	40	50	60	70	80	90	100

7/8	52	104	156	206						
1	68	135	202							

*The horse-power that may be transmitted by iron ropes is one half of the above.*

This table gives the amount of horse-power transmitted by wire ropes under maximum safe working tensions. In using wood-lined sheaves, therefore, it is well to make some allowance for the stretching of the rope, and to advocate somewhat heavier equipments than the above table would give; that is, if it is desired to transmit 20 horse-power, for instance, to put in a plant that would transmit 25 to 30 horse-power, thus avoiding the necessity of having to take up a comparatively small amount of stretch. On rubber and leather filling, however, the amount of power capable of being transmitted is 40 per cent greater than for wood, so that this filling is generally used, and in this case no allowance need be made for stretch, as such sheaves will likely transmit the power given by the table, under all possible deflections of the rope.

Under ordinary conditions, ropes of seven wires to the strand, laid about a hemp core, are best adapted to the transmission of power, but conditions often occur where 12- or 19-wire rope is to be preferred, as stated below.

**Deflections of the Rope.**—The tension of the rope is measured by the amount of sag or deflection at the centre of the span, and the deflection corresponding to the maximum safe working tension is determined by the following formulæ, in which  $S$  represents the span in feet:

	Steel Rope.	Iron Rope.
Def. of still rope at centre, in feet....	$h = .00004S^2$	$h = .00008S^2$
“ driving “ “ “ ....	$h_1 = .000025S^2$	$h_1 = .00005S^2$
“ slack “ “ “ ....	$h_2 = .0000875S^2$	$h_2 = .000175S^2$

**Limits of Span.**—On spans of less than sixty feet, it is impossible to splice the rope to such a degree of nicety as to give exactly the required deflection, and as the rope is further subject to a certain amount of stretch, it becomes necessary in such cases to apply mechanical means for producing the proper tension, in order to avoid frequent splicing, which is very objectionable; but care should always be exercised in using such tightening devices that they do not become the means, in unskilled hands, of overstraining the rope. The rope also is more sensitive to every irregularity in the sheaves and the fluctuations in the amount of power transmitted, and is apt to sway to such an extent beyond the narrow limits of the required deflections as to cause a jerking motion, which is very injurious. For this reason on very short spans it is found desirable to use a considerably heavier rope than that actually required to transmit the power; or in other words, instead of a 7-wire rope corresponding to the conditions of maximum tension, it is better to use a 19-wire rope of the same size wires, and to run this under a tension considerably below the maximum. In this way is obtained the advantages of increased weight and less stretch, without

having to use larger sheaves, while the wear will be greater in proportion to the increased surface.

In determining the maximum limit of span, the contour of the ground and the available height of the terminal sheaves must be taken into consideration. It is customary to transmit the power through the lower portion of the rope, as in this case the greatest deflection in this portion occurs when the rope is at rest. When running, the lower portion rises and the upper portion sinks, thus enabling obstructions to be avoided which otherwise would have to be removed, or make it necessary to erect very high towers. The maximum limit of span in this case is determined by the maximum deflection that may be given to the upper portion of the rope when running, which for sheaves of 10 ft. diameter is about 600 feet.

Much greater spans than this, however, are practicable where the contour of the ground is such that the upper portion of the rope may be the driver, and there is nothing to interfere with the proper deflection of the under portion. Some very long transmissions of power have been effected in this way without an intervening support, one at Lockport, N. Y., having a clear span of 1700 feet.

**Long-distance Transmissions.**—When the distance exceeds the limit for a clear span, intermediate supporting sheaves are used, with plain grooves (not filled), the spacing and size of which will be governed by the contour of the ground and the special conditions involved. The size of these sheaves will depend on the angle of the bend, gauged by the tangents to the curves of the rope at the points of inflection. If the curvature due to this angle and the working tension, regardless of the size of the sheaves, as determined by the table on the next page, is less than that of the minimum sheave (see table p. 919) the intermediate sheaves should not be smaller than such minimum sheave, but if the curvature is greater, smaller intermediate sheaves may be used.

In very long transmissions of power, requiring numerous intermediate supports, it is found impracticable to run the rope at the high speeds maintained in "flying transmissions." The rope therefore is run under a higher working tension, made practicable by wrapping it several times about grooved terminal drums, with a lap about a sheave on a take-up or counter-weighted carriage, which preserves a constant tension in the slack portion.

**Inclined Transmissions.**—When the terminal sheaves are not on the same elevation, the tension at the upper sheave will be greater than that at the lower, but this difference is so slight, in most cases, that it may be ignored. The span to be considered is the horizontal distance between the sheaves, and the principles governing the limits of span will hold good in this case, so that for very steep inclinations it becomes necessary to resort to tightening devices for maintaining the requisite tension in the rope. The limiting case of inclined transmissions occurs when one wheel is directly above the other. The rope in this case produces no tension whatever on the lower wheel, while the upper is subject only to the weight of the rope, which is usually so insignificant that it may be neglected altogether, and on vertical transmissions, therefore, mechanical tension is an absolute necessity.

**Bending Curvature of Wire Ropes.**—The curvature due to any bend in a wire rope is dependent on the tension, and is not always the same as the sheave in contact, but may be greater, which explains how it is that large ropes are frequently run around comparatively small sheaves without detriment, since it is possible to place these so close that the bending angle on each will be such that the resulting curvature will not over-strain the wires. This curvature may be ascertained from the formula and table on the next page, which give the theoretical radii of curvature in inches for various sizes of ropes and different angles for one pound tension in the rope. Dividing these figures by the actual tension in pounds, gives the radius of curvature assumed by the rope in cases where this exceeds the curvature of the sheave. The rigidity of the rope or internal friction of the wires and core has not been taken into account in these figures, but the effect of this is insignificant, and it is on the safe side to ignore it. By the "angle of bend" is meant the angle between the tangents to the curves of the rope at the points of inflection. When the rope is straight the angle is 180°. For angles less than 160° the radius of curvature in most cases will be less than that corresponding to the safe working tension, and the proper size of sheave to use in such cases will be governed by the table headed "Diameters of Minimum Sheaves Corresponding to a Maximum Safe Working Tension" on page 919.

### Radius of Curvature of Wire Ropes in Inches for 1-lb. Tension.

Formula:  $R = E\delta^4n \div 5.25t \cos \frac{1}{2}\theta$ ; in which  $R$  = radius of curvature;  
 $E$  = modulus of elasticity = 28,500,000;  $\delta$  = diameter of wires;  $n$  = no.  
of wires;  $\theta$  = angle of bend;  $t$  = working stress (lbs. and ins.).

Divide by stress in pounds to obtain radius in inches.

### ROPE-DRIVING.

The transmission of power by cotton or manila ropes is a competitor with gearing and leather belting when the amount of power is large, or the distance between the power and the work is comparatively great. The following is condensed from a paper by C. W. Hunt, Trans. A. S. M. E., xii. 230.

But few accurate data are available, on account of the long period required in each experiment, a rope lasting from three to six years. Installations which have been successful, as well as those in which the wear of the rope was destructive, indicate that 200 lbs. on a rope one inch in diameter is a safe and economical working strain. When the strain is materially increased, the wear is rapid.

In the following equations

$C$  = circumference of rope in inches;  $g$  = gravity;  
 $D$  = sag of the rope in inches;  $H$  = horse-power;  
 $F$  = centrifugal force in pounds;  $L$  = distance between pulleys in feet;  
 $P$  = pounds per foot of rope;  $w$  = working strain in pounds;  
 $R$  = force in pounds doing useful work;  
 $S$  = strain in pounds on the rope at the pulley;  
 $T$  = tension in pounds of driving side of the rope;  
 $t$  = tension in pounds on slack side of the rope;  
 $v$  = velocity of the rope in feet per second;  
 $W$  = ultimate breaking strain in pounds.

$$W = 720C^2; \quad P = .032C^2; \quad w = 20C^2.$$

This makes the normal working strain equal to 1/36 of the breaking strength, and about 1/25 of the strength at the splice. The actual strains are ordinarily much greater, owing to the vibrations in running, as well as from imperfectly adjusted tension mechanism.

For this investigation we assume that the strain on the driving side of a rope is equal to 200 lbs. on a rope one inch in diameter, and an equivalent strain for other sizes, and that the rope is in motion at various velocities of from 10 to 140 ft. per second.

The centrifugal force of the rope in running over the pulley will reduce

the amount of force available for the transmission of power. The centrifugal force  $F = Pv^2 \div g$ .

At a speed of about 80 ft. per second, the centrifugal force increases faster than the power from increased velocity of the rope, and at about 140 ft. per second equals the assumed allowable tension of the rope. Computing this force at various speeds and then subtracting it from the assumed maximum tension, we have the force available for the transmission of power. The whole of this force cannot be used, because a certain amount of tension on the slack side of the rope is needed to give adhesion to the pulley. What tension should be given to the rope for this purpose is uncertain, as there are no experiments which give accurate data. It is known from considerable experience that when the rope runs in a groove whose sides are inclined toward each other at an angle of 45° there is sufficient adhesion when the ratio of the tensions  $T \div t = 2$ .

For the present purpose,  $T$  can be divided into three parts: 1. Tension doing useful work; 2. Tension from centrifugal force; 3. Tension to balance the strain for adhesion.

The tension  $t$  can be divided into two parts: 1. Tension for adhesion; 2. Tension from centrifugal force.

It is evident, however, that the tension required to do a given work should not be materially exceeded during the life of the rope.

There are two methods of putting ropes on the pulleys; one in which the ropes are single and spliced on, being made very taut at first, and less so as the rope lengthens, stretching until it slips, when it is respliced. The other method is to wind a single rope over the pulley as many turns as needed to obtain the necessary horse-power and put a tension pulley to give the necessary adhesion and also take up the wear. The tension  $t$  required to transmit the normal horse-power for the ordinary speeds and sizes of rope is computed by formula (1), below. The total tension  $T$  on the driving side of the rope is assumed to be the same at all speeds. The centrifugal force, as well as an amount equal to the tension for adhesion on the slack side of the rope, must be taken from the total tension  $T$  to ascertain the amount of force available for the transmission of power.

It is assumed that the tension on the slack side necessary for giving adhesion is equal to one half the force doing useful work on the driving side of the rope; hence the force for useful work is  $R = \frac{2(T - F)}{3}$ ; and the tension on the slack side to give the required adhesion is  $\frac{1}{3}(T - F)$ . Hence

$$t = \frac{(T - F)}{3} + F. . . . . (1)$$

The sum of the tensions  $T$  and  $t$  is not the same at different speeds, as the equation (1) indicates.

As  $F$  varies as the square of the velocity, there is, with an increasing speed of the rope, a decreasing useful force, and an increasing total tension,  $t$ , on the slack side.

With these assumptions of allowable strains the horse-power will be

$$H = \frac{2v(T - F)}{3 \times 550} . . . . . (2)$$

Transmission ropes are usually from 1 to 1¾ inches in diameter. A computation of the horse-power for four sizes at various speeds and under ordinary conditions, based on a maximum strain equivalent to 200 lbs. for a rope one inch in diameter, is given in Fig. 166. The horse-power of other sizes is readily obtained from these. The maximum power is transmitted, under the assumed conditions, at a speed of about 80 feet per second.

The wear of the rope is both internal and external; the internal is caused by the movement of the fibres on each other, under pressure in bending over the sheaves, and the external is caused by the slipping and the wedging in the grooves of the pulley. Both of these causes of wear are, within the limits of ordinary practice, assumed to be directly proportional to the speed. Hence, if we assume the coefficient of the wear to be  $k$ , the wear will be  $kv$ , in which the wear increases directly as the velocity, but the horse-power that can be transmitted, as equation (2) shows, will not vary at the same rate.

The rope is supposed to have the strain  $T$  constant at all speeds on the driving side, and in direct proportion to the area of the cross-section; hence

the catenary of the driving side is not affected by the speed or by the diameter of the rope.

The deflection of the rope between the pulleys on the slack side varies with each change of the load or change of the speed, as the tension equation (1) indicates.

The deflection of the rope is computed for the assumed value of  $T$  and  $t$ .

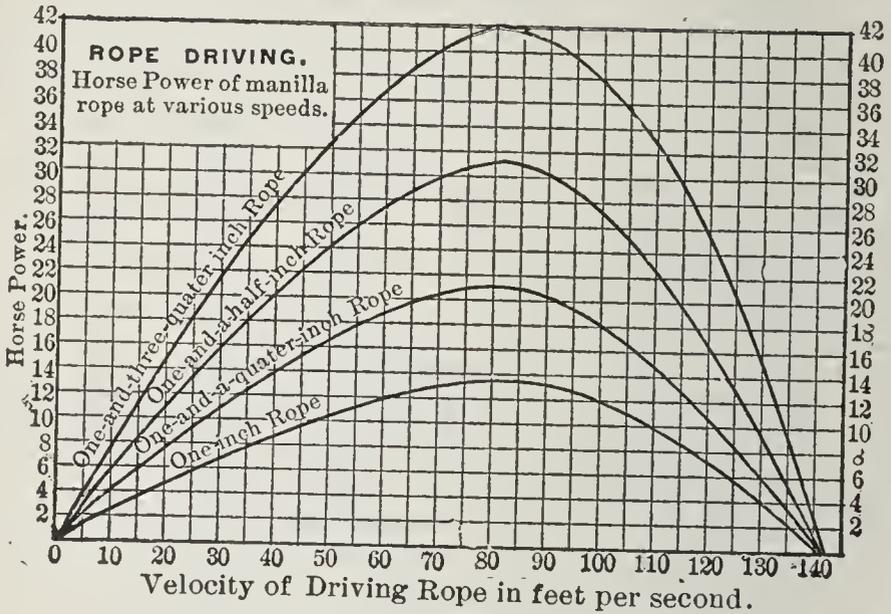

FIG. 166.

by the parabolic formula  $S = \frac{PL^2}{8D} + PD$ ,  $S$  being the assumed strain  $T$  on the driving side, and  $t$ , calculated by equation (1), on the slack side. The tension  $t$  varies with the speed.

**Horse-power of Transmission Rope at Various Speeds.**

Computed from formula (2), given above.

Diam. of Ropes.	Speed of the Rope in feet per minute.											Smallest Diam. of Pulleys in inches

The following notes are from the circular of the C. W. Hunt Co., New York :

For a temporary installation, when the rope is not to be long in use, it might be advisable to increase the work to double that given in the table.

For convenience in estimating the necessary clearance on the driving and on the slack sides, we insert a table showing the sag of the rope at different speeds when transmitting the horse-power given in the preceding table. When at rest the sag is not the same as when running, being greater on the driving and less on the slack sides of the rope. The sag of the driving side when transmitting the normal horse-power is the same no matter what size of rope is used or what the speed driven at, because the assumption is that the strain on the rope shall be the same at all speeds when transmitting the

assumed horse-power, but on the slack side the strains, and consequently the sag, vary with the speed of the rope and also with the horse-power. The table gives the sag for three speeds. If the actual sag is less than given in the table, the rope is strained more than the work requires.

This table is only approximate, and is exact only when the rope is running at its normal speed, transmitting its full load and strained to the assumed amount. All of these conditions are varying in actual work, and the table must be used as a guide only.

### Sag of the Rope between Pulleys.

Distance between Pulleys in feet.	Driving Side.		Slack Side of Rope.					
	All Speeds.		80 ft. per sec.		60 ft. per sec.		40 ft. per sec.	
40	0 feet 4 inches		0 feet 7 inches		0 feet 9 inches		0 feet 11 inches	
60	0 " 10 "		1 " 5 "		1 " 8 "		1 " 11 "	
80	1 " 5 "		2 " 4 "		2 " 10 "		3 " 3 "	
100	2 " 0 "		3 " 8 "		4 " 5 "		5 " 2 "	
120	2 " 11 "		5 " 3 "		6 " 3 "		7 " 4 "	
140	3 " 10 "		7 " 2 "		8 " 9 "		9 " 9 "	
160	5 " 1 "		9 " 3 "		11 " 3 "		14 " 0 "	

The size of the pulleys has an important effect on the wear of the rope—the larger the sheaves, the less the fibres of the rope slide on each other, and consequently there is less internal wear of the rope. The pulleys should not be less than forty times the diameter of the rope for economical wear, and as much larger as it is possible to make them. This rule applies also to the idle and tension pulleys as well as to the main driving-pulley.

The angle of the sides of the grooves in which the rope runs varies, with different engineers, from 45° to 60°. It is very important that the sides of these grooves should be carefully polished, as the fibres of the rope rubbing on the metal as it comes from the lathe tools will gradually break fibre by fibre, and so give the rope a short life. It is also necessary to carefully avoid all sand or blow holes, as they will cut the rope out with surprising rapidity.

Much depends also upon the arrangement of the rope on the pulleys, especially where a tension weight is used. Experience shows that the increased wear on the rope from bending the rope first in one direction and then in the other is similar to that of wire rope. At mines where two cages are used, one being hoisted and one lowered by the same engine doing the same work, the wire ropes, cut from the same coil, are usually arranged so that one rope is bent continuously in one direction and the other rope is bent first in one direction and then in the other, in winding on the drum of the engine. The rope having the opposite bends wears much more rapidly than the other, lasting about three quarters as long as its mate. This difference in wear shows in manila rope, both in transmission of power and in coal-hoisting. The pulleys should be arranged, as far as possible, to bend the rope in one direction.

### TENSION ON THE SLACK PART OF THE ROPE.

Speed of Rope, in feet per second.	Diameter of the Rope and Pounds Tension on the Slack Rope.								
	½	⅝	¾	⅞	1	1¼	1½	1¾	2
20	10	27	40	54	71	110	162	216	283
30	14	29	42	56	74	115	170	226	296
40	15	31	45	60	79	123	181	240	315
50	16	33	49	65	85	132	195	259	339
60	18	36	53	71	93	145	214	285	373
70	19	39	59	78	101	158	236	310	406
80	21	43	64	85	111	173	255	340	445
90	24	48	70	93	122	190	279	372	487

For large amounts of power it is common to use a number of ropes lying side by side in grooves, each spliced separately. For lighter drives some engineers use one rope wrapped as many times around the pulleys as is necessary to get the horse-power required, with a tension pulley to take up the slack as the rope wears when first put in use. The weight put upon this tension pulley should be carefully adjusted, as the overstraining of the rope from this cause is one of the most common errors in rope driving. We therefore give a table showing the proper strain on the rope for the various sizes, from which the tension weight to transmit the horse-power in the tables is easily deduced. This strain can be still further reduced if the horse-power transmitted is usually less than the nominal work which the rope was proportioned to do, or if the angle of groove in the pulleys is acute.

DIAMETER OF PULLEYS AND WEIGHT OF ROPE.

Diameter of Rope, in inches.	Smallest Diameter of Pulleys, in inches.	Length of Rope to allow for Splicing, in feet.	Approximate Weight, in lbs. per foot of rope.
$\frac{1}{2}$	20	6	.12
$\frac{5}{8}$	24	6	.18
$\frac{3}{4}$	30	7	.24
$\frac{7}{8}$	36	8	.32
1	42	9	.49
$1\frac{1}{4}$	54	10	.60
$1\frac{1}{2}$	60	12	.83
$1\frac{3}{4}$	72	13	1.10
2	84	14	1.40

With a given velocity of the driving-rope, the weight of rope required for transmitting a given horse-power is the same, no matter what size rope is adopted. The smaller rope will require more parts, but the weight will be the same.

**Miscellaneous Notes on Rope-driving.**—W. H. Booth communicates to the *Amer. Machinist* the following data from English practice with cotton ropes. The calculated figures are based on a total allowable tension: on a  $1\frac{3}{4}$ -inch rope of 600 lbs., and an initial tension of  $\frac{1}{10}$  the total allowed stress, which corresponds fairly with practice.

Diameter of rope.....	$1\frac{1}{4}$ "	$1\frac{3}{8}$ "	$1\frac{1}{2}$ "	$1\frac{5}{8}$ "	$1\frac{3}{4}$ "	$1\frac{7}{8}$ "	2"
Weight per foot, lbs.....	.5	.6	.72	.844	.98	1.125	1.3
Centrifugal tension = $V^2$ divided by	64	53	44	38	33	28	25
“ for $V = 80$ ft. per sec., lbs.	100	121	145	170	193	228	256
Total tension allowable.....	300	360	430	500	600	675	780
Initial tension.....	30	36	43	50	60	67	78
Net working tension at 80 ft. velocity	170	203	242	280	347	380	446
Horse-power per rope “ “	24	28	34	41	49	54	63

The most usual practice in Lancashire is summed up roughly in the following figures:  $1\frac{3}{4}$ -inch cotton ropes at 5000 ft. per minute velocity = 50 H. P. per rope. The most common sizes of rope now used are  $1\frac{3}{4}$  and  $1\frac{5}{8}$  in. The maximum horse-power for a given rope is obtained at about 80 to 83 feet per second. Above that speed the power is reduced by centrifugal tension. At a speed of 2500 ft. per minute four ropes will do about the same work as three at 5000 ft. per min.

Cotton ropes do not require much lubrication in the sense that it is required by ropes made of the rough fibre of manila hemp. Merely a slight surface dressing is all that is required. For small ropes, common in spinning machinery, from  $\frac{1}{2}$  to  $\frac{3}{4}$  inch diameter, it is the custom to prevent the fluffing of the ropes on the surface by a light application of a mixture of black-lead and molasses,—but only enough should be used to lay the fibres,—put upon one of the pulleys in a series of light dabs.

Reuleaux's Constructor gives as the "specific capacity" of hemp rope in actual practice, that is, the horse-power transmitted per square inch of cross-section for each foot of linear velocity per minute, .004 to .002, the cross-section being taken as that due to the full outside diameter of the rope. For a  $1\frac{3}{4}$ -in. rope, with a cross-section of 2.405 sq. in., at a velocity of 5000 ft. per min., this gives a horse-power of from 24 to 48, as against 41.8 by Mr. Hunt's table and 49 by Mr. Booth's.

Reuleaux gives formulæ for calculating sources of loss in hemp-rope transmission due to (1) journal friction, (2) stiffness of ropes, and (3) creep of ropes. The constants in these formulæ are, however, uncertain from lack of experimental data. He calculates an average case giving loss of power due to journal friction = 4%, to stiffness 7.8%, and to creep 5%, or 16.8% in all, and says this is not to be considered higher than the actual loss.

Spencer Miller, in a paper entitled "A Problem in Continuous Rope-driving" (Trans. A. S. C. E., 1897), reviews the difficulties which occur in rope-driving, with a continuous rope from a large to a small pulley. He adopts the angle of 45° as a minimum angle to use on the smaller pulley, and recommends that the larger pulley be grooved with a wider angle to a degree such that the resistance to slipping is equal in both wheels. By doing this the effect of the tension weight is felt equally throughout all the slack strands of the rope-drive, hence the tight ropes pull equally. It is shown that when the wheels are grooved alike the strains in the various ropes may differ greatly, and to such a degree that danger is introduced, for while one-half the tension weight should represent the maximum strain on the slack rope, it is demonstrated in the paper that the actual maximum strain may be even four or six times as great.

In a drive such as is recommended, with a wide angle in the large sheave with the larger arc of contact, the conditions governing the ropes are the same as if the wheels were of the same diameter; and where the wheels are of the same diameter, with a proper tension weight, the ropes pull alike. It is claimed that by widening the angle of the large sheave not only is there no power lost, but there is actually a great gain in power transmitted. An example is given in which it is shown that in that instance the power transmitted is nearly doubled. Mr. Miller refers to a 250-horse-power drive which has been running ten years, the large pulley being grooved 60° and the smaller 45°. This drive was designed to use a 1¼-in. manila rope, but the grooves were made deep enough so that a ¾-in. rope would not bottom. In order to determine the value of the drive a common ¾-in. rope was put in at first, and lasted six years, working under a factor of safety of only 14. He recommends, however, the employment in continuous rope-driving of a factor of safety of not less than 20.

The Walker Company adopts a curved form of groove instead of one with straight sides inclined to each other at 45°. The curves are concave to the rope. The rope rests on the sides of the groove in driving and driven pulleys. In idler pulleys the rope rests on the bottom of the groove, which is semicircular. The Walker Company also uses a "differential" drum for heavy rope-drives, in which the grooves are contained each in a separate ring which is free to slide on the turned surface of the drum in case one rope pulls more than another.

A heavy rope-drive on the separate, or English, rope system is described and illustrated in *Power*, April, 1892. It is in use at the India Mill at Darwen, England. This mill was originally driven by gears, but did not prove successful, and rope-driving was resorted to. The 85,000 spindles and preparation are driven by a 2000-horse-power tandem compound engine, with cylinders 23 and 44 inches in diameter and 72-inch stroke, running at 54 revolutions per minute. The fly-wheel is 30 feet in diameter, weighs 65 tons, and is arranged with 30 grooves for 1¾-inch ropes. These ropes lead off to receiving-pulleys upon the several floors, so that each floor receives its power direct from the fly-wheel. The speed of the ropes is 5089 feet per minute, and five 7-foot receivers are used, the number of ropes upon each being proportioned to the amount of power required upon the several floors. Lambeth cotton ropes are used. (For much other information on this subject see "Rope-Driving," by J. J. Flather, John Wiley & Sons, 1895.)

## FRICTION AND LUBRICATION.

**Friction** is defined by Rankine as that force which acts between two bodies at their surface of contact so as to resist their sliding on each other, and which depends on the force with which the bodies are pressed together.

**Coefficient of Friction.**—The ratio of the force required to slide a body along a horizontal plane surface to the weight of the body is called the coefficient of friction. It is equivalent to the tangent of the *angle of repose*, which is the angle of inclination to the horizontal of an inclined plane on which the body will just overcome its tendency to slide. The angle is usually denoted by  $\theta$ , and the coefficient by  $f$ .  $f = \tan \theta$ .

**Friction of Rest and of Motion.**—The force required to start a body sliding is called the friction of rest, and the force required to continue its sliding after having started is called the friction of motion.

**Rolling Friction** is the force required to roll a cylindrical or spherical body on a plane or on a curved surface. It depends on the nature of the surfaces and on the force with which they are pressed together, but is essentially different from ordinary, or sliding, friction.

**Friction of Solids.**—Rennie's experiments (1829) on friction of solids, usually unlubricated and dry, led to the following conclusions:

1. The laws of sliding friction differ with the character of the bodies rubbing together.

2. The friction of fibrous material is increased by increased extent of surface and by time of contact, and is diminished by pressure and speed.

3. With wood, metal, and stones, within the limit of abrasion, friction varies only with the pressure, and is independent of the extent of surface, time of contact and velocity.

4. The limit of abrasion is determined by the hardness of the softer of the two rubbing parts.

5. Friction is greatest with soft and least with hard materials.

6. The friction of lubricated surfaces is determined by the nature of the lubricant rather than by that of the solids themselves.

**Friction of Rest.** (Rennie.)

Pressure, lbs. per square inch.	Values of $f$ .			
	Wrought iron on Wrought Iron.	Wrought on Cast Iron.	Steel on Cast Iron.	Brass on Cast Iron.
187	.25	.28	.30	.23
224	.27	.29	.33	.22
336	.31	.33	.35	.21
448	.38	.37	.35	.21
560	.41	.37	.36	.23
672	Abraded	.38	.40	.23
784	"	Abraded	Abraded	.23

**Law of Unlubricated Friction.**—A. M. Wellington, *Eng'g News*, April 7, 1888, states that the most important and the best determined of all the laws of unlubricated friction may be thus expressed:

The coefficient of unlubricated friction decreases materially with velocity, is very much greater at minute velocities of 0 +, falls very rapidly with minute increases of such velocities, and continues to fall much less rapidly with higher velocities up to a certain varying point, following closely the laws which obtain with lubricated friction.

**Friction of Steel Tires Sliding on Steel Rails.** (Westinghouse & Galton.)

Speed, miles per hour.....	10	15	25	38	45	50
Coefficient of friction.....	0.110	.087	.080	.051	.047	.040
Adhesion, lbs. per ton (2240 lbs.)	246	195	179	128	114	90

**Rolling Friction** is a consequence of the irregularities of form and the roughness of surface of bodies rolling one over the other. Its laws are not yet definitely established in consequence of the uncertainty which exists in experiment as to how much of the resistance is due to roughness of surface, how much to original and permanent irregularity of form, and how much to distortion under the load. (Thurston.)

**Coefficients of Rolling Friction.**—If  $R$  = resistance applied at the circumference of the wheel,  $W$  = total weight,  $r$  = radius of the wheel, and  $f$  = a coefficient,  $R = fW \div r$ .  $f$  is very variable. Coulomb gives .06 for wood, .005 for metal, where  $W$  is in pounds and  $r$  in feet. Tredgold made the value of  $f$  for iron on iron .002.

For wagons on soft soil Morin found  $f = .065$ , and on hard smooth roads .02.

A Committee of the Society of Arts (Clark, R. T. D.) reported a loaded omnibus to exhibit a resistance on various loads as below:

Pavement	Speed per hour.	Coefficient.	Resistance.
Granite.....	2.87 miles.	.007	17.41 per ton.
Asphalt.....	3.56 “	.0121	27.14 “
Wood.....	3.34 “	.0185	41.60 “
Macadam, gravelled.....	3.45 “	.0199	44.48 “
“ granite, new..	3.51 “	.0451	101.09 “

Thurston gives the value of  $f$  for ordinary railroads, .003, well-laid railroad track, .002; best possible railroad track, .001.

The few experiments that have been made upon the coefficients of rolling friction, apart from axle friction, are too incomplete to serve as a basis for practical rules. (Trautwine).

**Laws of Fluid Friction.**—For all fluids, whether liquid or gaseous, the resistance is (1) independent of the pressure between the masses in contact; (2) directly proportional to the area of rubbing-surface; (3) proportional to the square of the relative velocity at moderate and high speeds, and to the velocity nearly at low speeds; (4) independent of the nature of the surfaces of the solid against which the stream may flow, but dependent to some extent upon their degree of roughness; (5) proportional to the density of the fluid, and related in some way to its viscosity. (Thurston.)

The Friction of Lubricated Surfaces approximates to that of solid friction as the journal is run dry, and to that of fluid friction as it is flooded with oil.

Prof. Thurston says concerning the above figures that much better results are probably obtained in good practice with ordinary machinery. Those here given are so greatly modified by variations of speed, pressure, and temperature, that they cannot be taken as correct for general purposes.

**Average Coefficients of Friction.** Journal of cast iron in bronze bearing; velocity 720 feet per minute; temperature 70° F.; intermittent feed through an oil-hole. (Thurston on Friction and Lost Work.)

Oils.	Pressures. pounds per square inch.			
	8	16	32	48
Sperm, lard, neat's-foot, etc.	.159 to .250	.138 to .192	.086 to .141	.077 to .144
Olive, cotton-seed, rape, etc.	.160 “ .283	.107 “ .245	.101 “ .168	.079 “ .131
Cod and menhaden . . . . .	.248 “ .278	.124 “ .167	.097 “ .102	.081 “ .122
Mineral lubricating-oils. . . . .	.154 “ .261	.145 “ .233	.086 “ .178	.094 “ .222

With fine steel journals running in bronze bearings and continuous lubrication, coefficients far below those above given are obtained. Thus with sperm-oil the coefficient with 50 lbs. per square inch pressure was .0034; with 200 lbs., .0051; with 300 lbs. .0057.

For very low pressures, as in spindles, the coefficients are much higher. Thus Mr. Woodbury found, at a temperature of 100° and a velocity of 600 feet per minute,

Pressures, lbs. per sq. in.....	1	2	3	4	5
Coefficient....	.38	.27	.22	.18	.17

These high coefficients, however, and the great decrease in the coefficient at increased pressures are limited as a practical matter only to the smaller pressures which exist especially in spinning machinery, where the pressure is so light and the film of oil so thick that the viscosity of the oil is an important part of the total frictional resistance.

**Experiments on Friction of a Journal Lubricated by an Oil-bath** (reported by the Committee on Friction, Proc. Inst. M. E., Nov. 1883) show that the absolute friction, that is, the absolute tangential force per square inch of bearing, required to resist the tendency of the brass to go round with the journal, is nearly a constant under all loads, within ordinary working limits. Most certainly it does not increase in direct proportion to the load, as it should do according to the ordinary theory of solid friction. The results of these experiments seem to show that the friction of a perfectly lubricated journal follows the laws of liquid friction much more closely than those of solid friction. They show that under these circumstances the friction is nearly independent of the pressure per square inch, and that it increases with the velocity, though at a rate not nearly so rapid as the square of the velocity.

The experiments on friction at different temperatures indicate a great diminution in the friction as the temperature rises. Thus in the case of lard-oil, taking a speed of 450 revolutions per minute, the coefficient of friction at a temperature of 120° is only one third of what it was at a temperature of 60.

The journal was of steel, 4 inches diameter and 6 inches long, and a gun-metal brass, embracing somewhat less than half the circumference of the journal, rested on its upper side, on which the load was applied. When the bottom of the journal was immersed in oil, and the oil therefore carried under the brass by rotation of the journal, the greatest load carried with rape-oil was 573 lbs. per square inch, and with mineral oil 625 lbs.

In experiments with ordinary lubrication, the oil being fed in at the centre of the top of the brass, and a distributing groove being cut in the brass parallel to the axis of the journal, the bearing would not run cool with only 100 lbs. per square inch, the oil being pressed out from the bearing-surface and through the oil-hole, instead of being carried in by it. On introducing the oil at the sides through two parallel grooves, the lubrication appeared to be satisfactory, but the bearing seized with 380 lbs. per square inch.

When the oil was introduced through two oil-holes, one near each end of the brass, and each connected with a curved groove, the brass refused to take its oil or run cool, and seized with a load of only 200 lbs. per square inch.

With an oil-pad under the journal feeding rape-oil, the bearing fairly carried 551 lbs. Mr. Tower's conclusion from these experiments is that the friction depends on the quantity and uniformity of distribution of the oil, and may be anything between the oil-bath results and seizing, according to the perfection or imperfection of the lubrication. The lubrication may be very small, giving a coefficient of 1/100; but it appeared as though it could not be diminished and the friction increased much beyond this point without imminent risk of heating and seizing. The oil-bath probably represents the most perfect lubrication possible, and the limit beyond which friction cannot be reduced by lubrication; and the experiments show that with speeds of from 100 to 200 feet per minute, by properly proportioning the bearing-surface to the load, it is possible to reduce the coefficient of friction to as low as 1/1000. A coefficient of 1/1500 is easily attainable, and probably is frequently attained, in ordinary engine-bearings in which the direction of the force is rapidly alternating and the oil given an opportunity to get between the surfaces, while the duration of the force in one direction is not sufficient to allow time for the oil film to be squeezed out.

Observations on the behavior of the apparatus gave reason to believe that with perfect lubrication the speed of minimum friction was from 100 to 150 feet per minute, and that this speed of minimum friction tends to be higher with an increase of load, and also with less perfect lubrication. By the speed of minimum friction is meant that speed in approaching which from rest the friction diminishes, and above which the friction increases.

**Coefficients of Friction of Journal with Oil-bath.**—Abstract of results of Tower's experiments on friction (Proc. Inst. M. E., Nov. 1883). Journal, 4 in. diam., 6 in. long; temperature, 90° F.

**Coefficients of Friction of Motion and of Rest of a Journal.**—A cast-iron journal in steel boxes, tested by Prof. Thurston at a speed of rubbing of 150 feet per minute, with lard and with sperm oil, gave the following:

Pressures per sq. in., lbs.....	50	100	250	500	750	1000
Coeff., with sperm.....	.013	.008	.005	.004	.0043	.009
" " lard.....	.02	.0137	.0085	.0053	.0066	.0125

The coefficients at starting were:

With sperm.....	.07	.135	.14	.15	.185	.18
With lard.....	.07	.11	.11	.10	.12	.12

The coefficient at a speed of 150 feet per minute decreases with increase of pressure until 500 lbs. per sq. in. is reached; above this it increases. The coefficient at rest or at starting increases with the pressure throughout the range of the tests.

**Value of Anti-friction Metals.** (Denton.)—The various white metals available for lining brasses do not afford coefficients of friction lower than can be obtained with bare brass, but they are less liable to "overheating," because of the superiority of such material over bronze in ability to permit of abrasion or crushing, without excessive increase of friction.

Thurston (Friction and Lost Work) says that gun-bronze, Babbitt, and other soft white alloys have substantially the same friction; in other words, the friction is determined by the nature of the unguent and not by that of the rubbing-surfaces, when the latter are in good order. The soft metals run at higher temperatures than the bronze. This, however, does not necessarily indicate a serious defect, but simply deficient conductivity. The value of the white alloys for bearings lies mainly in their ready reduction to a smooth surface after any local or general injury by alteration of either surface or form.

**Cast-iron for Bearings.** (Joshua Rose.)—Cast iron appears to be an exception to the general rule, that the harder the metal the greater the resistance to wear, because cast iron is softer in its texture and easier to cut with steel tools than steel or wrought iron, but in some situations it is far more durable than hardened steel; thus when surrounded by steam it will wear better than will any other metal. Thus, for instance, experience has demonstrated that piston-rings of cast iron will wear smoother, better, and equally as long as those of steel, and longer than those of either wrought iron or brass, whether the cylinder in which it works be composed of brass, steel, wrought iron, or cast iron; the latter being the more noteworthy, since two surfaces of the same metal do not, as a rule, wear or work well together. So also slide-valves of brass are not found to wear so long or so smoothly as those of cast iron, let the metal of which the seating is composed be whatever it may; while, on the other hand, a cast iron slide-valve will wear longer of itself and cause less wear to its seat, if the latter is of cast iron, than if of steel, wrought iron, or brass.

**Friction of Metals under Steam-pressure.**—The friction of brass upon iron under steam-pressure is double that of iron upon iron. (G. H. Babcock, Trans. A. S. M. E., i. 151.)

**Morin's "Laws of Friction."**—1. The friction between two bodies is directly proportioned to the pressure; i.e., the coefficient is constant for all pressures.

2. The coefficient and amount of friction, pressure being the same, is independent of the areas in contact.

3. The coefficient of friction is independent of velocity, although static friction (friction of rest) is greater than the friction of motion.

*Eng'g News*, April 7, 1888, comments on these "laws" as follows: From 1831 till about 1876 there was no attempt worth speaking of to enlarge our knowledge of the laws of friction, which during all that period was assumed to be complete, although it was really worse than nothing, since it was for the most part wholly false. In the year first mentioned Morin began a series of experiments which extended over two or three years, and which resulted in the enunciation of these three "fundamental laws of friction," no one of which is even approximately true.

For fifty years these laws were accepted as axiomatic, and were quoted as such without question in every scientific work published during that whole period. Now that they are so thoroughly discredited it has been attempted to explain away their defects on the ground that they cover only a very limited range of pressures, areas, velocities, etc., and that Morin himself only announced them as true within the range of his conditions. It is now clearly established that there are no limits or conditions within which any one of them even approximates to exactitude, and that there are many conditions under which they lead to the wildest kind of error, while many of the constants were as inaccurate as the laws. For example, in Morin's "Table of Coefficients of Moving Friction of Smooth Plane Surfaces, perfectly lubricated," which may be found in hundreds of text-books now in use, the coefficient of wrought iron on brass is given as .075 to .103, which would make the rolling friction of railway trains 15 to 20 lbs. per ton instead of the 3 to 6 lbs. which it actually is.

General Morin, in a letter to the Secretary of the Institution of Mechanical Engineers, dated March 15, 1879, writes as follows concerning his experiments on friction made more than forty years before: "The results furnished by my experiments as to the relations between pressure, surface, and speed on the one hand, and sliding friction on the other, have always been regarded by myself, not as mathematical laws, but as close approximations to the truth, within the limits of the data of the experiments themselves. The same holds, in my opinion, for many other laws of practical mechanics, such as those of rolling resistance, fluid resistance, etc."

Prof. J. E. Denton (*Stevens Indicator*, July, 1890) says: It has been generally assumed that friction between lubricated surfaces follows the simple law that the amount of the friction is some fixed fraction of the pressure between the surfaces, such fraction being independent of the intensity of the pressure per square inch and the velocity of rubbing, between certain limits of practice, and that the fixed fraction referred to is represented by the coefficients of friction given by the experiments of Morin or obtained from experimental data which represent conditions of practical lubrication, such as those given in Webber's Manual of Power.

By the experiments of Thurston, Woodbury, Tower, etc., however, it appears that the friction between lubricated metallic surfaces, such as ma-

chine bearings, is not directly proportional to the pressure, is not independent of the speed, and that the coefficients of Morin and Webber are about tenfold too great for modern journals.

Prof. Denton offers an explanation of this apparent contradiction of authorities by showing, with laboratory testing-machine data, that Morin's laws hold for bearings lubricated by a restricted feed of lubricant, such as is afforded by the oil-cups common to machinery; whereas the modern experiments have been made with a surplus feed or superabundance of lubricant, such as is provided only in railroad-car journals, and a few special cases of practice.

That the low coefficients of friction obtained under the latter conditions are realized in the case of car-journals, is proved by the fact that the temperature of car-boxes remains at 100° at high velocities; and experiment shows that this temperature is consistent only with a coefficient of friction of a fraction of one per cent. Deductions from experiments on train resistance also indicate the same low degree of friction. But these low co-efficients do not account for the internal friction of steam-engines as well as do the co-efficients of Morin and Webber.

In *American Machinist*, Oct. 23, 1890, Prof. Denton says: Morin's measurement of friction of lubricated journals did not extend to light pressures. They apply only to the conditions of general shafting and engine work.

He clearly understood that there was a frictional resistance, due solely to the viscosity of the oil, and that therefore, for very light pressures, the laws which he enunciated did not prevail.

He applied his dynamometers to ordinary shaft-journals without special preparation of the rubbing-surfaces, and without resorting to artificial methods of supplying the oil.

Later experimenters have with few exceptions devoted themselves exclusively to the measurement of resistance practically due to viscosity alone. They have eliminated the resistance to which Morin confined his measurements, namely, the friction due to such contact of the rubbing-surfaces as prevail with a very thin film of lubricant between comparatively rough surfaces.

Prof. Denton also says (Trans. A. S. M. E., x. 518): "I do not believe there is a particle of proof in any investigation of friction ever made, that Morin's laws do not hold for ordinary practical oil-cups or restricted rates of feed."

**Laws of Friction of well-lubricated Journals.**—John Goodman (Trans. Inst. C. E. 1886, *Eng'g News*, Apr. 7 and 14, 1888), reviewing the results obtained from the testing-machines of Thurston, Tower, and Stroudley, arrives at the following laws:

LAWS OF FRICTION: WELL-LUBRICATED SURFACES.

(Oil-bath.)

1. The coefficient of friction with the surfaces efficiently lubricated is from 1/6 to 1/10 that for dry or scantily lubricated surfaces.
2. The coefficient of friction for moderate pressures and speeds varies approximately inversely as the normal pressure; the frictional resistance varies as the area in contact, the normal pressure remaining constant.
3. At very low journal speeds the coefficient of friction is abnormally high; but as the speed of sliding increases from about 10 to 100 ft. per min., the friction diminishes, and again rises when that speed is exceeded, varying approximately as the square root of the speed.
4. The coefficient of friction varies approximately inversely as the temperature, within certain limits, namely, just before abrasion takes place.

The evidence upon which these laws are based is taken from various modern experiments. That relating to Law 1 is derived from the "First Report on Friction Experiments," by Mr. Beauchamp Tower.

Method of Lubrication.	Coefficient of Friction.	Comparative Friction.
Oil-bath.....	.00139	1.00
Siphon lubricator.....	.0098	7.06
Pad under journal.....	.0090	6.48

With a load of 293 lbs. per sq. in. and a journal speed of 314 ft. per min. Mr. Tower found the coefficient of friction to be .0016 with an oil-bath, and

.0097, or six times as much, with a pad. The very low coefficients obtained by Mr. Tower will be accounted for by Law 2, as he found that the frictional resistance per square inch under varying loads is nearly constant, as below:

Load in lbs. per sq. in. ....	529	468	415	363	310	258	205	153	100
Frictional resist. per sq. in.	.416	.514	.498	.472	.464	.438	.43	.458	.45

The frictional resistance per square inch is the product of the coefficient of friction into the load per square inch on horizontal sections of the brass. Hence, if this product be a constant, the one factor must vary inversely as the other, or a high load will give a low coefficient, and *vice versa*.

For ordinary lubrication, the coefficient is more constant under varying loads; the frictional resistance then varies directly as the load, as shown by Mr. Tower in Table VIII of his report (Proc. Inst. M. E. 1883).

With respect to Law 3, A. M. Wellington (Trans. A. S. C. E. 1884), in experiments on journals revolving at very low velocities, found that the friction was then very great, and nearly constant under varying conditions of the lubrication, load, and temperature. But as the speed increased the friction fell slowly and regularly, and again returned to the original amount when the velocity was reduced to the same rate. This is shown in the following table:

Speed, feet per minute:	0+	2.16	3.33	4.86	8.82	21.42	35.37	53.01	89.28	106.02
Coefficient of friction:	.118	.094	.070	.069	.055	.047	.040	.035	.030	.026

It was also found by Prof. Kimball that when the journal velocity was increased from 6 to 110 ft. per minute, the friction was reduced 70%; in another case the friction was reduced 67% when the velocity was increased from 1 to 100 ft. per minute; but after that point was reached the coefficient varied approximately with the square root of the velocity.

The following results were obtained by Mr. Tower:

Feet per minute...	209	262	314	366	419	471	Nominal Load per sq. in.
Coeff. of friction..	.0010	.0012	.0013	.0014	.0015	.0017	520 lbs.
“ “	.0013	.0014	.0015	.0017	.0018	.002	468 “
“ “	.0014	.0015	.0017	.0019	.0021	.0024	415 “

The variation of friction with temperature is approximately in the inverse ratio, Law 4. Take, for example, Mr. Tower's results, at 262 ft. per minute:

Temp. F.	110°	100°	90°	80°	70°	60°
Observed .....	.0044	.0051	.006	.0073	.0092	.0119
Calculated....	.00451	.00518	.00608	.00733	.00964	.01252

This law does not hold good for pad or siphon lubrication, as then the coefficient of friction diminishes more rapidly for given increments of temperature, but on a gradually decreasing scale, until the normal temperature has been reached; this normal temperature increases directly as the load per sq. in. This is shown in the following table taken from Mr. Stroudley's experiments with a pad of rape oil:

Temp. F .....	105°	110°	115°	120°	125°	130°	135°	140°	145°
Coefficient.....	.022	.0180	.0160	.0140	.0125	.0115	.0110	.0106	.0102
Decrease of coeff. ....	.....	.0040	.0020	.0020	.0015	.0010	.0005	.0004	.0002

In the Galton-Westinghouse experiments it was found that with velocities below 100 ft. per min., and with low pressures, the frictional resistance varied directly as the normal pressure; but when a velocity of 100 ft. per min. was exceeded, the coefficient of friction greatly diminished; from the same experiments Prof. Kennedy found that the coefficient of friction for high pressures was sensibly less than for low.

**Allowable Pressures on Bearing-surfaces.** (Proc. Inst. M. E., May, 1883.)—The Committee on Friction experimented with a steel ring of

rectangular section, pressed between two cast-iron disks, the annular bearing-surfaces of which were covered with gun-metal, and were 12 in. inside diameter and 14 in. outside. The two disks were rotated together, and the steel ring was prevented from rotating by means of a lever, the holding force of which was measured. When oiled through grooves cut in each face of the ring and tested at from 50 to 130 revs. per min., it was found that a pressure of 75 lbs. per sq. in. of bearing-surface was as much as it would bear safely at the highest speed without seizing, although it carried 90 lbs. per sq. in. at the lowest speed. The coefficient of friction is also much higher than for a cylindrical bearing, and the friction follows the law of the friction of solids much more nearly than that of liquids. This is doubtless due to the much less perfect lubrication applicable to this form of bearing compared with a cylindrical one. The coefficient of friction appears to be about the same with the same load at all speeds, or, in other words, to be independent of the speed; but it seems to diminish somewhat as the load is increased, and may be stated approximately as  $1/20$  at 15 lbs. per sq. in., diminishing to  $1/30$  at 75 lbs. per sq. in.

The high coefficients of friction are explained by the difficulty of lubricating a collar-bearing. It is similar to the slide-block of an engine, which can carry only about one tenth the load per sq. in. that can be carried by the crank-pins.

In experiments on cylindrical journals it has been shown that when a cylindrical journal was lubricated from the side on which the pressure bore, 100 lbs. per sq. in. was the limit of pressure that it would carry; but when it came to be lubricated on the lower side and was allowed to drag the oil in with it, 600 lbs. per sq. in. was reached with impunity; and if the 600 lbs. per sq. in., which was reckoned upon the full diameter of the bearing, came to be reckoned on the sixth part of the circle that was taking the greater proportion of the load, it followed that the pressure upon that part of the circle amounted to about 1200 lbs. per sq. in.

In connection with these experiments Mr. Wicksteed states that in drilling-machines the pressure on the collars is frequently as high as 336 lbs. per sq. in., but the speed of rubbing in this case is lower than it was in any of the experiments of the Research Committee. In machines working very slowly and intermittently, as in testing-machines, very much higher pressures are admissible.

Mr. Adamson mentions the case of a heavy upright shaft carried upon a small footstep-bearing, where a weight of at least 20 tons was carried on a shaft of 5 in. diameter, or, say, 20 sq. in. area, giving a pressure of 1 ton per sq. in. The speed was 190 to 200 revs. per min. It was necessary to force the oil under the bearing by means of a pump. For heavy horizontal shafts, such as a fly-wheel shaft, carrying 100 tons on two journals, his practice for getting oil into the bearings was to flatten the journal along one side throughout its whole length to the extent of about an eighth of an inch in width for each inch in diameter up to 8 in. diameter; above that size rather less flat in proportion to the diameter. At first sight it appeared alarming to get a continuous flat place coming round in every revolution of a heavily loaded shaft; yet it carried the oil effectually into the bearing, which ran much better in consequence than a truly cylindrical journal without a flat side.

In thrust-bearings on torpedo-boats Mr. Thornycroft allows a pressure of never more than 50 lbs. per sq. in.

Prof. Thurston (*Friction and Lost Work*, p. 240) says 7000 to 9000 lbs. pressure per square inch is reached on the slow-working and rarely-moved pivots of swing bridges.

Mr. Tower says (*Proc. Inst. M. E.*, Jan. 1884): In eccentric-pins of punching and shearing-machines very high pressures are sometimes used without seizing. In addition to the alternation in the direction, the pressure is applied for only a very short space of time in these machines, so that the oil has no time to be squeezed out.

In the discussion on Mr. Tower's paper (*Proc. Inst. M. E.* 1885) it was stated that it is well known from practical experience that with a constant load on an ordinary journal it is difficult and almost impossible to have more than 200 lbs. per square inch, otherwise the bearing would get hot and the oil go out of it; but when the motion was reciprocating, so that the load was alternately relieved from the journal, as with crank-pins and similar journals, much higher loads might be applied than even 700 or 800 lbs. per square inch.

Mr. Goodman (Proc. Inst. C. E. 1886) found that the total frictional resistance is materially reduced by diminishing the width of the brass.

The lubrication is most efficient in reducing the friction when the brass subtends an angle of from  $130^{\circ}$  to  $60^{\circ}$ . The film is probably at its best between the angles  $80^{\circ}$  and  $110^{\circ}$ .

In the case of a brass of a railway axle-bearing where an oil-groove is cut along its crown and an oil-hole is drilled through the top of the brass into it, the wear is invariably on the off side, which is probably due to the oil escaping as soon as it reaches the crown of the brass, and so leaving the off side almost dry, where the wear consequently ensues.

In railway axles the brass wears always on the forward side. The same observation has been made in marine-engine journals, which always wear in exactly the reverse way to what they might be expected. Mr. Stroudley thinks this peculiarity is due to a film of lubricant being drawn in from the under side of the journal to the aft part of the brass, which effectually lubricates and prevents wear on that side; and that when the lubricant reaches the forward side of the brass it is so attenuated down to a wedge shape that there is insufficient lubrication, and greater wear consequently follows.

Prof. J. E. Denton (*Am. Mach.*, Oct. 30, 1890) says: Regarding the pressure to which oil is subjected in railroad car-service, it is probably more severe than in any other class of practice. Car brasses, when used bare, are so imperfectly fitted to the journal, that during the early stages of their use the area of bearing may be but about one square inch. In this case the pressure per square inch is upwards of 6000 lbs. But at the slowest speeds of freight service the wear of a brass is so rapid that, within about thirty minutes the area is either increased to about three inches, and is thereby able to relieve the oil so that the latter can successfully prevent overheating of the journal, or else overheating takes place with *any oil*, and measures of relief must be taken which eliminate the question of differences of lubricating power among the different lubricants available. A brass which has been run about fifty miles under 5000 lbs. load may have extended the area of bearing-surface to about three square inches. The pressure is then about 1700 lbs. per square inch. It may be assumed that this is an average minimum area for car-service where no violent and unmanageable overheating has occurred during the use of a brass for a short time. This area will very slowly increase with any lubricant.

C. J. Field (*Power*, Feb. 1893) says: One of the most vital points of an engine for electrical service is that of main bearings. They should have a surface velocity of not exceeding 350 feet per minute, with a mean bearing-pressure per square inch of projected area of journal of not more than 80 lbs. This is considerably within the safe limit of cool performance and easy operation. If the bearings are designed in this way, it would admit the use of grease on all the main wearing-surface, which in a large type of engines for this class of work we think advisable.

**Oil-pressure in a Bearing.**—Mr. Beauchamp Tower (Proc. Inst. M. E. Jan. 1885) made experiments with a brass bearing 4 inches diameter by 6 inches long, to determine the pressure of the oil between the brass and the journal. The bearing was half immersed in oil, and had a total load of 8008 lbs. upon it. The journal rotated 150 revolutions per minute. The pressure of the oil was determined by drilling small holes in the bearing at different points and connecting them by tubes to a Bourdon gauge. It was found that the pressure varied from 310 to 625 lbs. per square inch, the greatest pressure being a little to the "off" side of the centre line of the top of the bearing, in the direction of motion of the journal. The sum of the upward force exerted by these pressures for the whole lubricated area was nearly equal to the total pressure on the bearing. The speed was reduced from 150 to 20 revolutions, but the oil-pressure remained the same, showing that the brass was as completely oil-borne at the lower speed as at the higher. The following was the observed friction at the lower speed:

Nominal load, lbs. per square inch...	443	333	211	89
Coefficient of friction.....	.00132	.00168	.00247	.0044

The nominal load per square inch is the total load divided by the product of the diameter and length of the journal. At the same low speed of 20 revolutions per minute it was increased to 676 lbs. per square inch without any signs of heating or seizing.

**Friction of Car-journal Brasses.** (J. E. Denton, Trans. A. S. M. E., xii. 405.)—A new brass dressed with an emery-wheel, loaded with 5000 lbs., may have an actual bearing-surface on the journal, as shown by the polish

of a portion of the surface, of only 1 square inch. With this pressure of 5000 lbs. per square inch, the coefficient of friction may be 6%, and the brass may be overheated, scarred and cut but, on the contrary, it may wear down evenly to a smooth bearing, giving a highly polished area of contact of 3 square inches, or more, inside of two hours of running, gradually decreasing the pressure per square inch of contact, and a coefficient of friction of less than 0.5%. A reciprocating motion in the direction of the axis is of importance in reducing the friction. With such polished surfaces any oil will lubricate, and the coefficient of friction then depends on the viscosity of the oil. With a pressure of 1000 lbs. per square inch, revolutions from 170 to 320 per minute, and temperatures of 75° to 113° F. with both sperm and paraffine oils, a coefficient of as low as 0.11% has been obtained, the oil being fed continuously by a pad.

**Experiments on Overheating of Bearings.—Hot Boxes.**

(Denton.)—Tests with car brasses loaded from 1100 to 4500 lbs. per square inch gave 7 cases of overheating out of 32 trials. The tests show how purely a matter of chance is the overheating, as a brass which ran hot at 5000 lbs. load on one day would run cool on a later date at the same or higher pressure. The explanation of this apparently arbitrary difference of behavior is that the accidental variations of the smoothness of the surfaces, almost infinitesimal in their magnitude, cause variations of friction which are always tending to produce overheating, and it is solely a matter of chance when these tendencies preponderate over the lubricating influence of the oil. There is no appreciable advantage shown by sperm-oil, when there is no tendency to overheat—that is, paraffine can lubricate under the highest pressures which occur, as well as sperm, when the surfaces are within the conditions affording the minimum coefficients of friction.

Sperm and other oils of high heat-resisting qualities, like vegetable oil and petroleum cylinder stocks, only differ from the more volatile lubricants, like paraffine, in their ability to reduce the chances of the continual accidental infinitesimal abrasion producing overheating.

The effect of emery or other gritty substance in reducing overheating of a bearing is thus explained:

The effect of the emery upon the surfaces of the bearings is to cover the latter with a series of parallel grooves, and apparently after such grooves are made the presence of the emery does not practically increase the friction over the amount of the latter when pure oil only is between the surfaces. The infinite number of grooves constitute a very perfect means of insuring a uniform oil supply at every point of the bearings. As long as grooves in the journal match with those in the brasses the friction appears to amount to only about 10% to 15% of the pressure. But if a smooth journal is placed between a set of brasses which are grooved, and pressure be applied, the journal crushes the grooves and becomes brazed or coated with brass, and then the coefficient of friction becomes upward of 40%. If then emery is applied, the friction is made very much less by its presence, because the grooves are made to match each other, and a uniform oil supply prevails at every point of the bearings, whereas before the application of the emery many spots of the latter receive no oil between them.

**Moment of Friction and Work of Friction of Sliding-surfaces, etc.**

	Moment of Friction, inch-lbs.	Energy lost by Friction in ft.-lbs. per min.
Flat surfaces.....	.....	$fWS$
Shafts and journals.....	$\frac{1}{2}fWd$	$.2618fWdn$
Flat pivots.....	$\frac{2}{3}fWr$	$.349fWrn$
Collar-bearing.....	$\frac{2}{3}fW \frac{r_2^3 - r_1^3}{r_2^2 - r_1^2}$	$.349fWrn \frac{r_2^3 - r_1^3}{r_2^2 - r_1^2}$
Conical pivot.....	$\frac{2}{3}fWr \operatorname{cosec} a$	$.349fWrn \operatorname{cosec} a$
Conical journal.....	$\frac{2}{3}fWr \sec a$	$.349fWrn \sec a$
Truncated-cone pivot.....	$\frac{2}{3}fW \frac{r_2^3 - r_1^3}{r_2 \sin a}$	$.349fW \frac{r_2^3 - r_1^3}{r_2 \sin a}$
Hemispherical pivot.....	$fWr$	$.5236fWrn$
Tractrix, or Schiele's "anti-friction" pivot.....	$fWr$	$.5236fWrn$

In the above  $f$  = coefficient of friction;  
 $W$  = weight on journal or pivot in pounds;  
 $r$  = radius,  $d$  = diameter, in inches;  
 $S$  = space in feet through which sliding takes place;  
 $r_2$  = outer radius,  $r_1$  = inner radius;  
 $n$  = number of revolutions per minute;  
 $\alpha$  = the half-angle of the cone, i.e., the angle of the slope with the axis.

To obtain the horse-power, divide the quantities in the last column by 33,000. Horse-power absorbed by friction of a shaft =  $\frac{fWdn}{126050}$ .

The formula for energy lost by shafts and journals is approximately true for loosely fitted bearings. Prof. Thurston shows that the correct formula varies according to the character of fit of the bearing; thus for loosely fitted journals, if  $U$  = the energy lost,

$$U = \frac{2f\pi r}{\sqrt{1+f^2}} Wn \text{ inch-pounds} = \frac{.2618fWdn}{\sqrt{1+f^2}} \text{ foot-lbs.}$$

For perfectly fitted journals  $U = 2.54f\pi r Wn$  inch-lbs. =  $.3325fWdn$ , ft.-lbs.

For a bearing in which the journal is so grasped as to give a uniform pressure throughout,  $U = f\pi^2 r Wn$  inch-lbs. =  $.4112fWdn$ , ft.-lbs.

Resistance of railway trains and wagons due to friction of trains:

$$\text{Pull on draw-bar} = \frac{f \times 2240}{R} \text{ pounds per gross ton,}$$

in which  $R$  is the ratio of the radius of the wheel to the radius of journal.

A cylindrical journal, perfectly fitted into a bearing, and carrying a total load, distributes the pressure due to this load unequally on the bearing, the maximum pressure being at the extremity of the vertical radius, while at the extremities of the horizontal diameter the pressure is zero. At any point of the bearing-surface at the extremity of a radius which makes an angle  $\theta$  with the vertical radius the normal pressure is proportional to  $\cos \theta$ . If  $p$  = normal pressure on a unit of surface,  $w$  = total load on a unit of length of the journal, and  $r$  = radius of journal,

$$w \cos \theta = 1.57rp, \quad p = \frac{w \cos \theta}{1.57r}.$$

### PIVOT-BEARINGS.

**The Schiele Curve.**—W. H. Harrison, in a letter to the *Am. Machinist*, 1891, says the Schiele curve is not as good a form for a bearing as the segment of a sphere. He says: A mill-stone weighing a ton frequently bears its whole weight upon the flat end of a hard-steel pivot  $1\frac{1}{8}$ " diameter, or one square inch area of bearing; but to carry a weight of 3000 lbs. he advises an end bearing about 4 inches diameter, made in the form of a segment of a sphere about  $\frac{1}{2}$  inch in height. The die or fixed bearing should be dished to fit the pivot. This form gives a chance for the bearing to adjust itself, which it does not have when made flat, or when made with the Schiele curve. If a side bearing is necessary it can be arranged farther up the shaft. The pivot and die should be of steel, hardened; cross-gutters should be in the die to allow oil to flow, and a central oil-hole should be made in the shaft.

The advantage claimed for the Schiele bearing is that the pressure is uniformly distributed over its surface, and that it therefore wears uniformly. Wilfred Lewis (*Am. Mach.*, April 19, 1894) says that its merits as a thrust-bearing have been vastly overestimated; that the term "anti-friction" applied to it is a misnomer, since its friction is greater than that of a flat step or collar of the same diameter. He advises that flat thrust-bearings should always be annular in form, having an inside diameter one half of the external diameter.

**Friction of a Flat Pivot-bearing.**—The Research Committee on Friction (Proc. Inst. M. E. 1891) experimented on a step-bearing, flat-ended, 3 in. diam., the oil being forced into the bearing through a hole in its centre and distributed through two radial grooves, insuring thorough lubrication. The step was of steel and the bearing of manganese-bronze.

At revolutions per min.....	50	128	194	290	353
The coefficient of friction varied	.0131	.0053	.0051	.0044	.0053
between					

With a white-metal bearing at 128 revolutions the coefficient of friction was a little larger than with the manganese-bronze. At the higher speeds the coefficient of friction was less, owing to the more perfect lubrication, as shown by the more rapid circulation of the oil. At 128 revolutions the bronze bearing heated and seized on one occasion with a load of 260 pounds and on another occasion with 300 pounds per square inch. The white-metal bearing under similar conditions heated and seized with a load of 240 pounds per square inch. The steel footstep on manganese-bronze was afterwards tried, lubricating with three and with four radial grooves; but the friction was from one and a half times to twice as great as with only the two grooves. (See also Allowable Pressures, page 936.)

**Mercury-bath Pivot.**—A nearly frictionless step-bearing may be obtained by floating the bearing with its superincumbent weight upon mercury. Such an apparatus is used in the lighthouses of La Heve, Havre. It is thus described in *Eng'g*, July 14, 1893, p. 41:

The optical apparatus, weighing about 1 ton, rests on a circular cast-iron table, which is supported by a vertical shaft of wrought iron 2.36 in. diameter.

This is kept in position at the top by a bronze ring and outer iron support, and at the bottom in the same way, while it rotates on a removable steel pivot resting in a steel socket, which is fitted to the base of the support. To the vertical shaft there is rigidly fixed a floating cast-iron ring 17.1 in. diameter and 11.8 in. in depth, which is plunged into and rotates in a mercury bath contained in a fixed outer drum or tank, the clearance between the vertical surfaces of the drum and ring being only 0.2 in., so as to reduce as much as possible the volume of mercury (about 220 lbs.), while the horizontal clearance at the bottom is 0.4 in.

### BALL-BEARINGS, FRICTION ROLLERS, ETC.

A. H. Tyler (*Eng'g*, Oct. 20, 1893, p. 483), after experiments and comparison with experiments of others arrives at the following conclusions:

That each ball must have two points of contact only.

The balls and race must be of glass hardness, and of absolute truth.

The balls should be of the largest possible diameter which the space at disposal will admit of.

Any one ball should be capable of carrying the total load upon the bearing.

Two rows of balls are always sufficient.

A ball-bearing requires no oil, and has no tendency to heat unless overloaded.

Until the crushing strength of the balls is being neared, the frictional resistance is proportional to the load.

The frictional resistance is inversely proportional to the diameter of the balls, but in what exact proportion Mr. Tyler is unable to say. Probably it varies with the square.

The resistance is independent of the number of balls and of the speed.

No rubbing action will take place between the balls, and devices to guard against it are unnecessary, and usually injurious.

The above will show that the ball-bearing is most suitable for high speeds and light loads. On the spindles of wood-carving machines some make as much as 30,000 revolutions per minute. They run perfectly cool, and never have any oil upon them. For heavy loads the balls should not be less than two thirds the diameter of the shaft, and are better if made equal to it.

**Ball-bearings** have not been found satisfactory for thrust-blocks, for the reason apparently that the tables crowd together. Better results have been obtained from coned rollers. A combined system of rollers and balls is described in *Eng'g*, Oct. 6, 1893, p. 429.

**Friction-rollers.**—If a journal instead of revolving on ordinary bearings be supported on friction-rollers the force required to make the journal revolve will be reduced in nearly the same proportion that the diameter of the axles of the rollers is less than the diameter of the rollers themselves. In experiments by A. M. Wellington with a journal  $3\frac{1}{2}$  in. diam. supported on rollers 8 in. diam., whose axles were  $1\frac{3}{4}$  in. diam., the friction in starting from rest was  $\frac{1}{4}$  the friction of an ordinary  $3\frac{1}{2}$ -in. bearing, but at a car speed of 10 miles per hour it was  $\frac{1}{2}$  that of the ordinary bearing. The ratio of the diam. of the axle to diam. of roller was  $1\frac{3}{4}:8$ , or as 1 to 4.6.

**Bearings for Very High Rotative Speeds.** (Proc. Inst. M. E., Oct. 1888, p. 482.)—In the Parsons steam-turbine, which has a speed of as high as 18,000 rev. per min., as it is impossible to secure absolute accuracy of balance, the bearings are of special construction so as to allow of a certain very small amount of lateral freedom. For this purpose the bearing is surrounded by two sets of steel washers 1/16 inch thick and of different diameters, the larger fitting close in the casing and about 1/32 inch clear of the bearing, and the smaller fitting close on the bearing and about 1/32 inch clear of the casing. These are arranged alternately, and are pressed together by a spiral spring. Consequently any lateral movement of the bearing causes them to slide mutually against one another, and by their friction to check or damp any vibrations that may be set up in the spindle. The tendency of the spindle is then to rotate about its axis of mass, or principal axis as it is called; and the bearings are thereby relieved from excessive pressure, and the machine from undue vibration. The finding of the centre of gyration, or rather allowing the turbine itself to find its own centre of gyration, is a well-known device in other branches of mechanics: as in the instance of the centrifugal hydro-extractor, where a mass very much out of balance is allowed to find its own centre of gyration; the faster it ran the more steadily did it revolve and the less was the vibration. Another illustration is to be found in the spindles of spinning machinery, which run at about 10,000 or 11,000 revolutions per minute: they are made of hardened and tempered steel, and although of very small dimensions, the outside diameter of the largest portion or driving whorl being perhaps not more than 1¼ in., it is found impracticable to run them at that speed in what might be called a hard-and-fast bearing. They are therefore run with some elastic substance surrounding the bearing, such as steel springs, hemp, or cork. Any elastic substance is sufficient to absorb the vibration, and permit of absolutely steady running.

**FRICION OF STEAM-ENGINES.**

**Distribution of the Friction of Engines.**—Prof. Thurston in his "Friction and Lost Work," gives the following:

	1.	2.	3.
Main bearings.....	47.0	35.4	35.0
Piston and rod.....	32.9	25.0	21.0
Crank-pin.....	6.8	5.1	13.0
Cross-head and wrist-pin.....	5.4	4.1	
Valve and rod.....	2.5	26.4	22.0
Eccentric strap.....	5.3	4.0	
Link and eccentric.....	....	....	9.01
Total....	100.0	100.0	100.0

No. 1, Straight-line, 6' × 12', balanced valve; No. 2, Straight-line, 6' × 12', unbalanced valve; No. 3, 7' × 10', Lansing traction locomotive valve-gear.

Prof. Thurston's tests on a number of different styles of engines indicate that the friction of any engine is practically constant under all loads. (Trans. A. S. M. E., viii. 86; ix. 74.)

In a Straight-line engine, 8' × 14', I.H.P. from 7.41 to 57.54, the friction H. P. varied irregularly between 1.97 and 4.02, the variation being independent of the load. With 50 H.P. on the brake the I.H.P. was only 52.6, the friction being only 2.6 H.P., or about 5%.

In a compound condensing-engine, tested from 0 to 102.6 brake H.P., gave I.H.P. from 14.92 to 117.8 H.P., the friction H.P. varying only from 14.92 to 17.42. At the maximum load the friction was 15.2 H.P., or 12.9%.

The friction increases with increase of the boiler-pressure from 30 to 70 lbs., and then becomes constant. The friction generally increases with increase of speed, but there are exceptions to this rule.

Prof. Denton (*Stevens Indicator*, July, 1890), comparing the calculated friction of a number of engines with the friction as determined by measurement, finds that in one case, a 75-ton ammonia ice-machine, the friction of the compressor, 17½ H.P., is accounted for by a coefficient of friction of 7½% on all the external bearings, allowing 6% of the entire friction of the machine for the friction of pistons, stuffing-boxes, and valves. In the case of the Pawtucket pumping-engine, estimating the friction of the external bearings with a coefficient of friction of 6% and that of the pistons, valves, and stuffing-boxes as in the case of the ice-machine, we have the total friction distributed as follows:

	Horse-power.	Per cent of Whole.
Crank-pins and effect of piston-thrust on main shaft..	0.71	11.4
Weight of fly-wheel and main shaft.....	1.95	32.4
Steam-valves.....	0.23	3.7
Eccentric.....	0.07	1.2
Pistons.....	0.43	7.2
Stuffing-boxes, six altogether .....	0.72	11.3
Air-pump.....	2.10	32.8
Total friction of engine with load.....	6.21	100.0
Total friction per cent of indicated power ...	4.27	

The friction of this engine, though very low in proportion to the indicated power, is satisfactorily accounted for by Morin's law used with a coefficient of friction of 5%. In both cases the main items of friction are those due to the weight of the fly-wheel and main shaft and to the piston-thrust on crank-pins and main-shaft bearings. In the ice-machine the latter items are the larger owing to the extra crank-pin to work the pumps, while in the Pawtucket engine the former preponderates, as the crank-thrusts are partly absorbed by the pump-pistons, and only the surplus effect acts on the crank-shaft.

Prof. Denton describes in *Trans. A. S. M. E.*, x, 392, an apparatus by which he measured the friction of a piston packing-ring. When the parts of the piston were thoroughly devoid of lubricant, the coefficient of friction was found to be about 7½%; with an oil-feed of one drop in two minutes the coefficient was about 5%; with one drop per minute it was about 3%. These rates of feed gave unsatisfactory lubrication, the piston groaning at the ends of the stroke when run slowly, and the flow of oil left upon the surfaces was found by analysis to contain about 50% of iron. A feed of two drops per minute reduced the coefficient of friction to about 1%, and gave practically perfect lubrication, the oil retaining its natural color and purity.

## LUBRICATION.

**Measurement of the Durability of Lubricants.** (J. E. Denton, *Trans. A. S. M. E.*, xi, 1013.)—Practical differences of durability of lubricants depend not on any differences of inherent ability to resist being "worn out" by rubbing, but upon the rate at which they flow through and away from the bearing-surfaces. The conditions which control this flow are so delicate in their influence that all attempts thus far made to measure durability of lubricants may be said to have failed to make distinctions of lubricating value having any practical significance. In some kinds of service the limit to the consumption of oil depends upon the extent to which dust or other refuse becomes mixed with it, as in railroad-car lubrication and in the case of agricultural machinery. The economy of one oil over another, so far as the quality used is concerned—that is, so far as durability is concerned—is simply proportional to the rate at which it can insinuate itself into and flow out of minute orifices or cracks. Oils will differ in their ability to do this, first, in proportion to their viscosity, and, second, in proportion to the capillary properties which they may possess by virtue of the particular ingredients used in their composition. Where the thickness of film between rubbing-surfaces must be so great that large amounts of oil pass through bearings in a given time, and the surroundings are such as to permit oil to be fed at high temperatures or applied by a method not requiring a perfect fluidity, it is probable that the least amount of oil will be used when the viscosity is as great as in the petroleum cylinder stocks. When, however, the oil must flow freely at ordinary temperatures and the feed of oil is restricted, as in the case of crank-pin bearings, it is not practicable to feed such heavy oils in a satisfactory manner. Oils of less viscosity or of a fluidity approximating to lard-oil must then be used.

**Relative Value of Lubricants.** (J. E. Denton, *Am. Mach.*, Oct. 30, 1890.)—The three elements which determine the value of a lubricant are the cost due to consumption of lubricants, the cost spent for coal to overcome the frictional resistance caused by use of the lubricant, and the cost due to the metallic wear on the journal and the brasses.

**The Qualifications of a Good Lubricant,** as laid down by W. H. Bailey, in *Proc. Inst. C. E.*, vol. xlv., p. 372, are: 1. Sufficient body to keep the surfaces free from contact under maximum pressure. 2. The

greatest possible fluidity consistent with the foregoing condition. 3. The lowest possible coefficient of friction, which in bath lubrication would be for fluid friction approximately. 4. The greatest capacity for storing and carrying away heat. 5. A high temperature of decomposition. 6. Power to resist oxidation or the action of the atmosphere. 7. Freedom from corrosive action on the metals upon which used.

**Amount of Oil needed to Run an Engine.**—The Vacuum Oil Co. in 1892, in response to an inquiry as to cost of oil to run a 1000-H.P. Corliss engine, wrote: The cost of running two engines of equal size of the same make is not always the same. Therefore while we could furnish figures showing what it is costing some of our customers having Corliss engines of 1000 H.P., we could only give a general idea, which in itself might be considerably out of the way as to the probable cost of cylinder-and engine-oils per year for a particular engine. Such an engine ought to run readily on less than 8 drops of 600 W oil per minute. If 3000 drops are figured to the quart, and 8 drops used per minute, it would take about two and one half barrels (52.5 gallons) of 600 W cylinder-oil, at 65 cents per gallon, or about \$85 for cylinder-oil per year, running 6 days a week and 10 hours a day. Engine-oil would be even more difficult to guess at what the cost would be, because it would depend upon the number of cups required on the engine, which varies somewhat according to the style of the engine. It would doubtless be safe, however, to calculate at the outside that not more than twice as much engine-oil would be required as of cylinder-oil.

The Vacuum Oil Co. in 1892 published the following results of practice with "600 W" cylinder-oil:

Corliss compound engine,	{	20 and 33 × 48; 83 revs. per min.; 1 drop of oil per min. to 1 drop in two minutes.
“ triple exp. “	{	20, 33, and 46 × 48; 1 drop every 2 minutes.
Porter-Allen	{	20 and 36 × 36; 143 revs. per min.; 2 drops of oil per min., reduced afterwards to 1 drop per min.
Ball	{	15 × 25 × 16; 240 revs. per min.; 1 drop every 4 minutes.

Results of tests on ocean-steamers communicated to the author by Prof. Denton in 1892 gave: for 1200-H.P. marine engine, 5 to 6 English gallons (6 to 7.2 U. S. gals.) of engine-oil per 24 hours for external lubrication; and for a 1500-H.P. marine engine, triple expansion, running 75 revs. per min., 6 to 7 English gals. per 24 hours. The cylinder-oil consumption is exceedingly variable,—from 1 to 4 gals. per day on different engines, including cylinder-oil used to swab the piston-rods.

**Quantity of Oil used on a Locomotive Crank-pin.**—Prof. Denton, *Trans. A. S. M. E.*, xi. 1020, says: A very economical case of practical oil-consumption is when a locomotive main crank-pin consumes about six cubic inches of oil in a thousand miles of service. This is equivalent to a consumption of one milligram to seventy square inches of surface rubbed over.

**The Examination of Lubricating-oils.** (Prof. Thos. B. Stillman, *Stevens Indicator*, July, 1890.)—The generally accepted conditions of a good lubricant are as follows:

1. "Body" enough to prevent the surfaces, to which it is applied, from coming in contact with each other. (Viscosity.)
2. Freedom from corrosive acid, either of mineral or animal origin.
3. As fluid as possible consistent with "body."
4. A minimum coefficient of friction.
5. High "flash" and burning points.
6. Freedom from all materials liable to produce oxidation or "gumming."

The examinations to be made to verify the above are both chemical and mechanical, and are usually arranged in the following order:

1. Identification of the oil, whether a simple mineral oil, or animal oil, or a mixture.
2. Density.
3. Viscosity.
4. Flash-point.
5. Burning-point.
6. Acidity.
7. Coefficient of friction.
8. Cold test.

Detailed directions for making all of the above tests are given in Prof. Stillman's Article. See also Stillman's *Engineering Chemistry*, p. 366.

**Notes on Specifications for Petroleum Lubricants.** (C. M. Everest, Vice-Pres. Vacuum Oil Co., Proc. Engineering Congress, Chicago World's Fair, 1893.)—The specific gravity was the first standard established for determining quality of lubricating oils, but it has long since been discarded as a conclusive test of lubricating quality. However, as the specific gravity of a particular petroleum oil increases the viscosity also increases.

The object of the fire test of a lubricant, as well as its flash test, is the prevention of danger from fire through the use of an oil that will evolve inflammable vapors. The lowest fire test permissible is 300°, which gives a liberal factor of safety under ordinary conditions.

The cold test of an oil, i. e., the temperature at which the oil will congeal, should be well below the temperature at which it is used; otherwise the coefficient of friction would be correspondingly increased.

Viscosity, or fluidity, of an oil is usually expressed in seconds of time in which a given quantity of oil will flow through a certain orifice at the temperature stated, comparison sometimes being made with water, sometimes with sperm-oil, and again with rape seed oil. It seems evident that within limits the lower the viscosity of an oil (without a too near approach to metallic contact of the rubbing surfaces) the lower will be the coefficient of friction. But we consider that each bearing in a mill or factory would probably require an oil of different viscosity from any other bearing in the mill, in order to give its lowest coefficient of friction, and that slight variations in the condition of a particular bearing would change the requirements of that bearing; and further, that when nearing the "danger point" the question of viscosity alone probably does not govern.

The requirement of the New England Manufacturers' Association, that an oil shall not lose over 5% of its volume when heated to 140° Fahr. for 12 hours, is to prevent losses by evaporation, with the resultant effects.

The precipitation test gives no indication of the quality of the oil itself, as the free carbon in improperly manufactured oils can be easily removed.

It is doubtful whether oil buyers who require certain given standards of laboratory tests are better served than those who do not. Some of the standards are so faulty that to pass them an oil manufacturer must supply oil he knows to be faulty; and the requirements of the best standards can generally be met by products that will give inferior results in actual service.

**Penna. R. R. Specifications for Petroleum Products, 1900.**—Five different grades of petroleum products will be used.

The materials desired under this specification are the products of the distillation and refining of petroleum unmixed with any other substances.

**150° Fire-test Oil.**—This grade of oil will not be accepted if sample (1) is not "water-white" in color; (2) flashes below 130° Fahrenheit; (3) burns below 151° Fahrenheit; (4) is cloudy or shipment has cloudy barrels when received, from the presence of glue or suspended matter; (5) becomes opaque or shows cloud when the sample has been 10 minutes at a temperature of 0° Fahrenheit.

**300° Fire-test Oil.**—This grade of oil will not be accepted if sample (1) is not "water-white" in color; (2) flashes below 249° Fahrenheit; (3) burns below 298° Fahrenheit; (4) is cloudy or shipment has cloudy barrels when received, from the presence of glue or suspended matter; (5) becomes opaque or shows cloud when the sample has been 10 minutes at a temperature of 32° Fahrenheit; (6) shows precipitation when some of the sample is heated to 450° F. The precipitation test is made by having about two fluid ounces of the oil in a six-ounce beaker, with a thermometer suspended in the oil, and then heating slowly until the thermometer shows the required temperature. The oil changes color, but must show no precipitation.

**Paraffine and Neutral Oils.**—These grades of oil will not be accepted if the sample from shipment (1) is so dark in color that printing with long-primer type cannot be read with ordinary daylight through a layer of the oil  $\frac{1}{2}$  inch thick; (2) flashes below 298° F.; (3) has a gravity at 60° F., below 24° or above 35° Baumé; (4) from October 1st to May 1st has a cold test above 10° F., and from May 1st to October 1st has a cold test above 32° F.

The color test is made by having a layer of the oil of the prescribed thickness in a proper glass vessel, and then putting the printing on one side of the vessel and reading it through the layer of oil with the back of the observer toward the source of light.

**Well Oil.**—This grade of oil will not be accepted if the sample from shipment (1) flashes, from May 1st to October 1st, below 298° F., or, from October 1st to May 1st, below 249° F.; (2) has a gravity at 60° F., below 28° or above 31° Baumé; (3) from October 1st to May 1st has a cold test above 10° F., and from May 1st to October 1st has a cold test above 32° F.; (4) shows any precipitation when 5 cubic centimetres are mixed with 95 c. c. of gasoline. The precipitation test is to exclude tarry and suspended matter. It is made by putting 95 c. c. of 88° B gasoline, which must not be above 80° F. in temperature, into a 100 c. c.

graduate, then adding the prescribed amount of oil and shaking thoroughly. Allow to stand ten minutes. With satisfactory oil no separated or precipitated material can be seen.

500° Fire-test Oil.—This grade of oil will not be accepted if sample from shipment (1) flashes below 494° F.; (2) shows precipitation with gasoline when tested as described for well oil.

Printed directions for determining flashing and burning tests and for making cold tests and taking gravity are furnished by the railroad company.

A, freight cars; engine oil on shifting-engines; miscellaneous greasing in foundries, etc. B, cylinder lubricant on marine equipment and on stationary engines. C, engine oil; all engine machinery; engine and tender truck boxes; shafting and machine tools; bolt cutting; general lubrication except cars. D, passenger-car lubrication. E, cylinder lubricant for locomotives. C<sub>1</sub>, D<sub>1</sub>, for use in Dec., Jan., and Feb.; C<sub>2</sub>, D<sub>2</sub>, in March, April, May, Sept., Oct., and Nov.; C<sub>3</sub>, D<sub>3</sub>, in June, July, and August. Weights per gallon, A, 7.4 lbs.; B, C, D, E, 7.5 lbs.

**Soda Mixture for Machine Tools.** (Penna. R. R. 1894.)—Dissolve 5 lbs. of common sal-soda in 40 gallons of water and stir thoroughly. When needed for use mix a gallon of this solution with about a pint of engine oil. Used for the cutting parts of machine tools instead of oil.

## SOLID LUBRICANTS.

**Graphite** in a condition of powder and used as a *solid lubricant*, so called, to distinguish it from a liquid lubricant, has been found to do well where the latter has failed.

Rennie, in 1829, says: "Graphite lessened friction in all cases where it was used." General Morin, at a later date, concluded from experiments that it could be used with advantage under heavy pressures; and Prof. Thurston found it well adapted for use under both light and heavy pressures when mixed with certain oils. It is especially valuable to prevent abrasion and cutting under heavy loads and at low velocities.

**Soapstone**, also called talc and steatite, in the form of powder and mixed with oil or fat, is sometimes used as a lubricant. Graphite or soapstone, mixed with soap, is used on surfaces of wood working against either iron or wood.

**Fibre-graphite.**—A new self-lubricating bearing known as fibre-graphite is described by John H. Cooper in Trans. A. S. M. E., xiii. 374, as the invention of P. H. Holmes, of Gardiner, Me. This bearing material is composed of selected natural graphite, which has been finely divided and freed from foreign and gritty matter, to which is added wood-fibre or other growth mixed in water in various proportions, according to the purpose to be served, and then solidified by pressure in specially prepared moulds; after removal from which the bearings are first thoroughly dried, then saturated with a drying oil, and finally subjected to a current of hot, dry air for the purpose of oxidizing the oil, and hardening the mass. When finished, they may be "machined" to size or shape with the same facility and means employed on metals. (Holmes Fibre-Graphite Mfg. Co., Philadelphia.)

**Metaline** is a solid compound, usually containing graphite, made in the form of small cylinders which are fitted permanently into holes drilled in the surface of the bearing. The bearing thus fitted runs without any other lubrication. (North American Metaline Co., Long Island City, N. Y.)

## THE FOUNDRY.

### CUPOLA PRACTICE.

The following notes, with the accompanying table, are taken from an article by Simpson Bolland in *American Machinist*, June 30, 1892. The table shows heights, depth of bottom, quantity of fuel on bed, proportion of fuel and iron in charges, diameter of main blast-pipes, number of tuyeres, blast-pressure, sizes of blowers and power of engines, and melting capacity per hour, of cupolas from 24 inches to 84 inches in diameter.

*Capacity of Cupola.*—The accompanying table will be of service in determining the capacity of cupola needed for the production of a given quantity of iron in a specified time.

First, ascertain the amount of iron which is likely to be needed at each cast, and the length of time which can be devoted profitably to its disposal; and supposing that two hours is all that can be spared for that purpose, and that ten tons is the amount which must be melted, find in the column, Melting Capacity per hour in Pounds, the nearest figure to five tons per hour, which is found to be 10,760 pounds per hour, opposite to which in the column Diameter of Cupolas, Inside Lining, will be found 48 inches; this will be the size of cupola required to furnish ten tons of molten iron in two hours.

Or suppose that the heats were likely to average 6 tons, with an occasional increase up to ten, then it might not be thought wise to incur the extra expense consequent on working a 48-inch cupola, in which case, by following the directions given, it will be found that a 40-inch cupola would answer the purpose for 6 tons, but would require an additional hour's time for melting whenever the 10-ton heat came along.

The quotations in the table are not supposed to be all that can be melted in the hour by some of the very best cupolas, but are simply the amounts which a common cupola under ordinary circumstances may be expected to melt in the time specified.

*Height of Cupola.*—By height of cupola is meant the distance from the base to the bottom side of the charging hole.

*Depth of Bottom of Cupola.*—Depth of bottom is the distance from the sand-bed, after it has been formed at the bottom of the cupola, up to the under side of the tuyeres.

All the amounts for fuel are based upon a bottom of 10 inches deep, and any departure from this depth must be met by a corresponding change in the quantity of fuel used on the bed; more in proportion as the depth is increased, and less when it is made shallower.

*Amount of Fuel Required on the Bed.*—The column "Amount of Fuel required on Bed, in Pounds" is based on the supposition that the cupola is a straight one all through, and that the bottom is 10 inches deep. If the bottom be more, as in those of the Colliau type, then additional fuel will be needed.

The amounts being given in pounds, answer for both coal and coke, for, should coal be used, it would reach about 15 inches above the tuyeres; the same weight of coke would bring it up to about 22 inches above the tuyeres, which is a reliable amount to stock with.

*First Charge of Iron.*—The amounts given in this column of the table are safe figures to work upon in every instance, yet it will always be in order, after proving the ability of the bed to carry the load quoted, to make a slow and gradual increase of the load until it is fully demonstrated just how much burden the bed will carry.

*Succeeding Charges of Fuel and Iron.*—In the columns relating to succeeding charges of fuel and iron, it will be seen that the highest proportions are not favored, for the simple reason that successful melting with any greater proportion of iron to fuel is not the rule, but, rather, the exception. Whenever we see that iron has been melted in prime condition in the proportion of 12 pounds of iron to one of fuel, we may reasonably expect that the talent, material, and cupola have all been up to the highest degree of excellence.

*Diameter of Main Blast-pipe.*—The table gives the diameters of main blast-pipes for all cupolas from 24 to 84 inches diameter. The sizes given opposite each cupola are of sufficient area for all lengths up to 100 feet.

Cupola Practice.

Diam. of Cu- pola inside Inches.	Height of Cu- pola from bot'm plate to bottom of charging door. Feet.	Depth, from sanded to under side of Tuyeres. Inches.	Amt of Fuel required in Pounds. **Tuyeres for Cupola.**—Two columns are devoted to the number and sizes of tuyeres requisite for the successful working of each cupola; one gives the number of pipes 6 inches diameter, and the other gives the number and dimensions of rectangular tuyeres which are their equivalent in area.

From these two columns any other arrangement or disposition of tuyeres may be made, which shall answer in their totality to the areas given in the table.

When cupolas exceed 60 inches in diameter, the increase in diameter should begin somewhere above the tuyeres. This method is necessary in all common cupolas above 60 inches, because it is not possible to force the blast to the middle of the stock, effectively, at any greater diameter.

On no consideration must the tuyere area be reduced; thus, an 84-inch cupola must have tuyere area equal to 31 pipes 6 inches diameter, or 16 flat tuyeres 16 inches by  $13\frac{1}{2}$  inches.

If it is found that the given number of flat tuyeres exceed in circumference that of the diminished part of the cupola, they can be shortened, allowing the decreased length to be added to the depth, or they may be built in on end; by so doing, we arrive at a modified form of the Blakeney cupola.

Another important point in this connection is to arrange the tuyeres in such a manner as will concentrate the fire at the melting-point into the smallest possible compass, so that the metal in fusion will have less space to traverse while exposed to the oxidizing influence of the blast.

To accomplish this, recourse has been had to the placing of additional rows of tuyeres in some instances—the “Stewart rapid cupola” having three rows, and the “Colliau cupola furnace” having two rows, of tuyeres.

**Blast-pressure.**—Experiments show that about 30,000 cubic feet of air are consumed in melting a ton of iron, which would weigh about 2400 pounds, or more than both iron and fuel. When the proper quantity of air is supplied, the combustion of the fuel is perfect, and carbonic-acid gas is the result. When the supply of air is insufficient, the combustion is imperfect, and carbonic-oxide gas is the result. The amount of heat evolved in these two cases is as 15 to  $4\frac{1}{2}$ , showing a loss of over two thirds of the heat by imperfect combustion.

It is not always true that we obtain the most rapid melting when we are forcing into the cupola the largest quantity of air. Some time is required to elevate the temperature of the air supplied to the point that it will enter into combustion. If more air than this is supplied, it rapidly absorbs heat, reduces the temperature, and retards combustion, and the fire in the cupola may be extinguished with too much blast.

**Slag in Cupolas.**—A certain amount of slag is necessary to protect the molten iron which has fallen to the bottom from the action of the blast; if it was not there, the iron would suffer from decarbonization.

When slag from any cause forms in too great abundance, it should be led away by inserting a hole a little below the tuyeres, through which it will find its way as the iron rises in the bottom.

In the event of clean iron and fuel, slag seldom forms to any appreciable extent in small heats; this renders any preparation for its withdrawal unnecessary, but when the cupola is to be taxed to its utmost capacity it is then incumbent on the melter to flux the charges all through the heat, carrying it away in the manner directed.

The best flux for this purpose is the chips from a white marble yard. About 6 pounds to the ton of iron will give good results when all is clean.

When fuel is bad, or iron is dirty, or both together, it becomes imperative that the slag be kept running all the time.

**Fuel for Cupolas.**—The best fuel for melting iron is coke, because it requires less blast, makes hotter iron, and melts faster than coal. When coal must be used, care should be exercised in its selection. All anthracites which are bright, black, hard, and free from slate, will melt iron admirably. The size of the coal used affects the melting to an appreciable extent, and, for the best results, small cupolas should be charged with the size called “egg,” a still larger grade for medium-sized cupolas, and what is called “lump” will answer for all large cupolas, when care is taken to pack it carefully on the charges.

**Charging a Cupola.**—Chas. A. Smith (*Am. Mach.*, Feb. 12, 1891) gives the following: A 28-in. cupola should have from 300 to 400 pounds of coke on bottom bed; a 36-in. cupola, 700 to 800 pounds; a 48-in. cupola, 1500 lbs.; and a 60-in. cupola should have one ton of fuel on bottom bed. To every pound of fuel on the bed, three, and sometimes four pounds of metal can be added with safety, if the cupola has proper blast; in after-charges, to every

pound of fuel add 8 to 10 pounds of metal; any well-constructed cupola will stand ten.

F. P. Wolcott (*Am. Mach.*, Mar. 5, 1891) gives the following as the practice of the Colwell Iron-works, Carteret, N. J.: "We melt daily from twenty to forty tons of iron, with an average of 11.2 pounds of iron to one of fuel. In a 36-in. cupola seven to nine pounds is good melting, but in a cupola that lines up 48 to 60 inches, anything less than nine pounds shows a defect in arrangement of tuyeres or strength of blast, or in charging up."

"The Moulder's Text-book," by Thos. D. West, gives forty-six reports in tabular form of cupola practice in thirty States, reaching from Maine to Oregon.

**Cupola Charges in Stove-foundries.** (*Iron Age*, April 14, 1892.)

No two cupolas are charged exactly the same. The amount of fuel on the bed or between the charges differs, while varying amounts of iron are used in the charges. Below will be found charging-lists from some of the prominent stove-foundries in the country :

<p><b>A</b>—Bed of fuel, coke..... lbs. 1,500                  First charge of iron ..... 5,000                  All other charges of iron.. 1,000                  First and second charges of coke, each ..... 200</p>	<p>Four next charges of coke, each ..... 150                  Six next charges of coke, each ..... 120                  Nineteen next charges of coke, each..... 100</p>
--	--

Thus for a melt of 18 tons there would be 5120 lbs. of coke used, giving a ratio of 7 to 1. Increase the amount of iron melted to 24 tons, and a ratio of 8 pounds of iron to 1 of coal is obtained.

<p><b>B</b>—Bed of fuel, coke..... lbs. 1,600                  First charge of iron..... 1,800                  First charge of fuel..... 150                  All other charges of iron, each.... 1,000</p>	<p>Second and third charges of fuel..... 130                  All other charges of fuel, each 100</p>
--	---

For an 18-ton melt 5060 lbs. of coke would be necessary, giving a ratio of 7.1 lbs. of iron to 1 pound of coke.

<p><b>C</b>—Bed of fuel, coke..... lbs. 1,600                  First charge of iron..... 4,000                  First and second charges of coke ... 200</p>	<p>All other charges of iron..... 2,000                  All other charges of coke..... 150</p>
--	---

In a melt of 18 tons 4100 lbs. of coke would be used, or a ratio of 8.5 to 1.

<p><b>D</b>—Bed of fuel, coke . . . . . lbs. 1,800                  First charge of iron..... 5,600</p>	<p>All charges of coke, each..... 200                  All other charges of iron..... 2,900</p>
---	---

In a melt of 18 tons, 3900 lbs. of fuel would be used, giving a ratio of 9.4 pounds of iron to 1 of coke. Very high, indeed, for stove-plate.

<p><b>E</b>—Bed of fuel, coal..... lbs. 1,900                  First charge of iron..... 5,000                  First charge of coal..... 200</p>	<p>All other charges of iron, each 2,000                  All other charges of coal, each 175</p>
---	---

In a melt of 18 tons 4700 lbs. of coal would be used, giving a ratio of 7.7 lbs. of iron to 1 lb. of coal.

These are sufficient to demonstrate the varying practices existing among different stove-foundries. In all these places the iron was proper for stove-plate purposes, and apparently there was little or no difference in the kind of work in the sand at the different foundries.

**Results of Increased Driving.** (*Erie City Iron-works*, 1891.)—

May—Dec. 1890: 60-in. cupola, 100 tons clean castings a week, melting 8 tons per hour; iron per pound of fuel, 7½ lbs.; per cent weight of good castings to iron charged, 75¾. Jan.—May, 1891: Increased rate of melting to 11½ tons per hour; iron per lb. fuel, 9½; per cent weight of good castings, 75; one week, 13¼ tons per hour, 10.3 lbs. iron per lb. fuel; per cent weight of good castings, 75.3. The increase was made by putting in an additional row of tuyeres and using stronger blast, 14 ounces. Coke was used as fuel. (W. O. Webber, *Trans. A. S. M. E.* xii. 1045.)

### Buffalo Steel Pressure-blowers, Speeds and Capacities as applied to Cupolas.

No. of Blower.	Square inches Blast.	Diam. inside of Cupola in inches.	Pressure in oz.	Speed—No. of Revs. per minute.	Melting Capacity in lbs. per hour.	Cubic Feet of Air required per minute.	Pressure in oz.	Speed—No. of Revs. per min	Melting Capacity in lbs. per hour.	Cubic Feet of Air required per minute.
4	4	20	8	4732	1545	666	9	5030	1647	717
5	6	25	8	4209	2321	773	10	4726	2600	867
6	8	30	8	3660	3093	951	10	4108	3671	1067
7	14	35	8	3244	4218	1486	10	3342	4777	1668
8	18	40	8	2948	5425	2199	10	3310	6082	2469
9	26	45	10	2785	7818	3203	12	3260	8598	3523
10	36	55	10	2195	11295	4938	12	2413	12378	5131
11	45	65	12	1952	16955	7707	14	2116	18357	8353
11½	55	72	12	1647	22607	10276	14	1797	25176	11144
12	75	84	12	1625	25836	11744	14	1775	28019	12736

In the table are given two different speeds and pressures for each size of blower, and the quantity of iron that may be melted, per hour, with each. In all cases it is recommended to use the lowest pressure of blast that will do the work. Run up to the speed given for that pressure, and regulate quantity of air by the blast-gate. The tuyere area should be at least one ninth of the area of cupola in square inches, with not less than four tuyeres at equal distances around cupola, so as to equalize the blast throughout. Variations in temperature affect the working of cupolas materially, hot weather requiring increase in volume of air.

(For tables of the Sturtevant blower see pages 519 and 520.)

**Loss in Melting Iron in Cupolas.**—G. O. Vair, *Am. Mach.*, March 5, 1891, gives a record of a 45-in. Colliau cupola as follows:

Ratio of fuel to iron, 1 to 7.42.

Good castings .....	21,314 lbs.
New scrap .....	3,005 "
Millings .....	200 "
Loss of metal .....	1,481 "

Amount melted..... 26,000 lbs.  
Loss of metal, 5.69%. Ratio of loss, 1 to 17.55.

**Use of Softeners in Foundry Practice.** (W. Graham, *Iron Age*, June 27, 1889.)—In the foundry the problem is to have the right proportions of combined and graphitic carbon in the resulting casting; this is done by getting the proper proportion of silicon. The variations in the proportions of silicon afford a reliable and inexpensive means of producing a cast iron of any required mechanical character which is possible with the material employed. In this way, by mixing suitable irons in the right proportions, a required grade of casting can be made more cheaply than by using irons in which the necessary proportions are already found.

If a strong machine casting were required, it would be necessary to keep the phosphorus, sulphur, and manganese within certain limits. Professor Turner found that cast iron which possessed the maximum of the desired qualities contained, graphite, 2.59%; silicon, 1.42%; phosphorus, 0.39%; sulphur, 0.06%; manganese, 0.58%.

A strong casting could not be made if there was much increase in the amount of phosphorus, sulphur, or manganese. Irons of the above percentages of phosphorus, sulphur, and manganese would be most suitable for this purpose, but they could be of different grades, having different percentages of silicon, combined and graphitic carbon. Thus hard irons, mottled and white irons, and even steel scrap, all containing low percentages of silicon and high percentages of combined carbon, could be employed if an iron having a large amount of silicon were mixed with them in sufficient amount. This would bring the silicon to the proper proportion and would cause the combined carbon to be forced into the graphitic state, and the resulting

casting would be soft. High-silicon irons used in this way are called "softeners."

The following are typical analyses of softeners:

	Ferro-silicon.				Softeners, American.			Scotch Irons, No. 1.	
	Foreign.		American.		Well-ston.	Globe	Belle-fonte.	Eg-linton	Colt-ness.
Silicon .....	10.55	9.80	12.08	10.34	6.67	5.89	3 to 6	2.15	2.59
Combined C..	1.84	0.69	0.06	0.07	....	0.30	0.25	0.21	.....
Graphitic C..	0.52	1.12	1.52	1.92	2.57	2.85	3.	3.76	.....
Manganese ..	3.86	1.95	0.76	0.52	...	1.00	0.53	2.80	1.70
Phosphorus..	0.04	0.21	0.48	0.45	0.50	1.10	0.35	0.62	0.85
Sulphur .....	0.03	0.04	Trace	Trace	Trace	0.02	0.03	0.03	0.01

(For other analyses, see pages 371 to 373.)

Ferro-silicons contain a low percentage of total carbon and a high percentage of combined carbon. Carbon is the most important constituent of cast iron, and there should be about 3.4% total carbon present. By adding ferro-silicon which contains only 2% of carbon the amount of carbon in the resulting mixture is lessened.

Mr. Keep found that more silicon is lost during the remelting of pig of over 10% silicon than in remelting pig iron of lower percentages of silicon. He also points out the possible disadvantage of using ferro-silicons containing as high a percentage of combined carbon as 0.70% to overcome the bad effects of combined carbon in other irons.

The Scotch irons generally contain much more phosphorus than is desired in irons to be employed in making the strongest castings. It is a mistake to mix with strong low-phosphorus irons an iron that would increase the amount of phosphorus for the sake of adding softening qualities, when softness can be produced by mixing irons of the same low phosphorus.

(For further discussion of the influence of silicon see page 365.)

**Shrinkage of Castings.**—The allowance necessary for shrinkage varies for different kinds of metal, and the different conditions under which they are cast. For castings where the thickness runs about one inch, cast under ordinary conditions, the following allowance can be made:

For cast-iron, $\frac{1}{8}$ inch per foot.	For zinc, $\frac{5}{16}$ inch per foot.
" brass, $\frac{3}{16}$ " " "	" tin, $\frac{1}{12}$ " " "
" steel, $\frac{1}{4}$ " " "	" aluminum, $\frac{3}{16}$ " " "
" mal. iron, $\frac{1}{8}$ " " "	" Britannia, $\frac{1}{32}$ " " "

Thicker castings, under the same conditions, will shrink less, and thinner ones more, than this standard. The quality of the material and the manner of moulding and cooling will also make a difference.

Numerous experiments by W. J. Keep (see Trans. A. S. M. E., vol. xvi.) showed that the shrinkage of cast iron of a given section decreases as the percentage of silicon increases, while for a given percentage of silicon the shrinkage decreases as the section is increased. Mr. Keep gives the following table showing the approximate relation of shrinkage to size and percentage of silicon:

Percentage of Silicon.	Sectional Area of Casting.					
	$\frac{1}{2}$ " □	1" □	1" × 2"	2" □	3" □	4" □
	Shrinkage in Decimals of an inch per foot of Length.					
1.	.183	.158	.146	.130	.113	.102
1.5	.171	.145	.133	.117	.098	.087
2.	.159	.133	.121	.104	.085	.074
2.5	.147	.121	.108	.092	.073	.060
3.	.135	.108	.095	.077	.059	.045
3.5	.123	.095	.082	.065	.046	.032

Mr. Keep also gives the following "approximate key for regulating foundry mixtures" so as to produce a shrinkage of 1/8 in. per ft. in castings of different sections:

Size of casting.....	1/2	1	2	3	4	in. sq.
Silicon required, per cent.....	3.25	2.75	2.25	1.75	1.25	per cent.
Shrinkage of a 1/2-in. test-bar.	.125	.135	.145	.155	.165	in. per ft.

**Weight of Castings determined from Weight of Pattern.**

(Rose's Pattern-maker's Assistant.)

A Pattern weighing One Pound, made of—	Will weigh when cast in

**Moulding Sand.** (From a paper on "The Mechanical Treatment of Moulding Sand," by Walter Bagshaw, Proc. Inst. M. E. 1891.)—The chemical composition of sand will affect the nature of the casting, no matter what treatment it undergoes. Stated generally, good sand is composed of 94 parts silica, 5 parts alumina, and traces of magnesia and oxide of iron. Sand containing much of the metallic oxides, and especially lime, is to be avoided. Geographical position is the chief factor governing the selection of sand; and whether weak or strong, its deficiencies are made up for by the skill of the moulder. For this reason the same sand is often used for both heavy and light castings, the proportion of coal varying according to the nature of the casting. A common mixture of facing-sand consists of six parts by weight of old sand, four of new sand, and one of coal-dust. Floor-sand requires only half the above proportions of new sand and coal-dust to renew it. German founders adopt one part by measure of new sand to two of old sand; to which is added coal-dust in the proportion of one tenth of the bulk for large castings, and one twentieth for small castings. A few founders mix street-sweepings with the coal in order to get porosity when the metal in the mould is likely to be a long time before setting. Plumbago is effective in preventing destruction of the sand; but owing to its refractory nature, it must not be dusted on in such quantities as to close the pores and prevent free exit of the gases. Powdered French chalk, soapstone, and other substances are sometimes used for facing the mould; but next to plumbago, oak charcoal takes the best place, notwithstanding its liability to float occasionally and give a rough casting.

For the treatment of sand in the moulding-shop the most primitive method is that of hand-riddling and treading. Here the materials are roughly proportioned by volume, and riddled over an iron plate in a flat heap, where the mixture is trodden into a cake by stamping with the feet; it is turned over with the shovel, and the process repeated. Tough sand can be obtained in this manner, its toughness being usually tested by squeezing a handful into a ball and then breaking it; but the process is slow and tedious. Other things being equal, the chief characteristics of a good moulding-sand are toughness and porosity, qualities that depend on the manner of mixing as well as on uniform ramming.

**Toughness of Sand.**—In order to test the relative toughness, sand mixed in various ways was pressed under a uniform load into bars 1 in. sq. and about 12 in. long, and each bar was made to project further and further over the edge of a table until its end broke off by its own weight. Old sand from the shop floor had very irregular cohesion, breaking at all lengths of projections from 1/2 in. to 1 1/2 in. New sand in its natural state held together until an overhang of 2 3/4 in. was reached. A mixture of old sand, new sand, and coal-dust

Mixed under rollers.....	broke at 2	to 2 1/4	in. of overhang.
“ in the centrifugal machine.....	“ “ 2	“ 2 1/4	“ “ “
“ through a riddle.....	“ “ 1 3/4	“ 2 1/8	“ “ “

Showing as a mean of the tests only slight differences between the last three methods, but in favor of machine-work. In many instances the fractures were so uneven that minute measurements were not taken.

**Dimensions of Foundry Ladles.**—The following table gives the dimensions, inside the lining, of ladles from 25 lbs. to 16 tons capacity. All the ladles are supposed to have straight sides. (*Am. Mach.*, Aug. 4, 1892.)

Capacity.	Diam.	Depth.	Capacity.	Diam.	Depth.

### THE MACHINE-SHOP.

#### SPEED OF CUTTING-TOOLS IN LATHES, MILLING MACHINES, ETC.

Relation of diameter of rotating tool or piece, number of revolutions, and cutting-speed :

Let  $d$  = diam. of rotating piece in inches,  $n$  = No. of revs. per min.;

$S$  = speed of circumference in feet per minute;

$$S = \frac{\pi dn}{12} = .2618dn; \quad n = \frac{S}{.2618d} = \frac{3.82S}{d}; \quad d = \frac{3.82S}{n}$$

Approximate rule: No. of revs. per min. =  $4 \times$  speed in ft. per min.  $\div$  diam. in inches.

**Speed of Cut for Lathes and Planers.** (Prof. Coleman Sellers, *Stevens' Indicator*, April, 1892.)—*Brass* may be turned at high speed like wood.

**Bronze.**—A speed of 18 feet per minute can be used with the soft alloys—say 8 to 1, while for hard mixtures a slow speed is required—say 6 feet per minute.

**Wrought Iron** can be turned at 40 feet per minute, but planing-machines that are used for both cast and forged iron are operated at 18 feet per minute.

**Machinery Steel.**—Ordinary, 14 feet per minute; car-axles, etc., 9 feet per minute.

**Wheel Tires.**—6 feet per minute; the tool stands well, but many prefer to run faster, say 8 to 10 feet, and grind the tool more frequently.

**Lathes.**—The speeds obtainable by means of the cone-pulley and the back gearing are in geometrical progression from the slowest to the fastest. In a well-proportioned machine the speeds hold the same relation through all the steps. Many lathes have the same speed on the slowest of the cone and the fastest of the back-gear speeds.

The *Speed of Counter-shaft* of the lathe is determined by an assumption of a slow speed with the back gear, say 6 feet per minute, on the largest diameter that the lathe will swing.

**EXAMPLE.**—A 30-inch lathe will swing 30 inches =, say, 90 inches circumference = 7' 6"; the lowest triple gear should give a speed of 5 or 6 per minute.

In turning or planing, if the cutting-speed exceed 30 ft. per minute, so much heat will be produced that the temper will be drawn from the tool. The speed of cutting is also governed by the thickness of the shaving, and by the hardness and tenacity of the metal which is being cut; for instance, in cutting mild steel, with a traverse of ¾ in. per revolution or stroke, and with a shaving about ⅝ in. thick, the speed of cutting must be reduced to about 8 ft. per minute. A good average cutting-speed for wrought or cast

iron is 20 ft. per minute, whether for the lathe, planing, shaping, or slotting machine. (Proc. Inst. M. E., April, 1883, p. 248.)

**Table of Cutting-speeds.**

Diameter, inches.	Feet per minute.									
	5	10	15	20	25	30	35	40	45	50

**Speed of Cutting with Turret Lathes.**—Jones & Lamson Machine Co. give the following cutting-speeds for use with their flat turret lathe on diameters not exceeding two inches:

		Ft. per minute.
Threading	{ Tool steel and taper on tubing.....	10
	{ Machinery.....	15
	{ Very soft steel.....	20
Turning machinery steel	{ Cut which reduces the stock to 1/2 of its original diam..	20
	{ Cut which reduces the stock to 3/4 of its original diam..	25
	{ Cut which reduces the stock to 7/8 of its original diam..	30 to 35
Turning very soft machinery steel, light cut and cool work....		40 to 45 50 to 60

**Forms of Metal-cutting Tools.**—"Hutte," the German Engineers' Pocket-book, gives the following cutting-angles for using least power:

	Top Rake.	Angle of Cutting-edge.
Wrought iron.....	3°	51°
Cast iron.....	4°	51°
Bronze.....	4°	66°

The *American Machinist* comments on these figures as follows: We are not able to give the best nor even the generally used angles for tools, because these vary so much to suit different circumstances, such as degree of hardness of the metal being cut, quality of steel of which the tool is made, depth of cut, kind of finish desired, etc. The angles that cut with the least expenditure of power are easily determined by a few experiments, but the best angles must be determined by good judgment, guided by experience. In nearly all cases, however, we think the best practical angles are greater than those given.

For illustrations and descriptions of various forms of cutting-tools, see articles on Lathe Tools in App. Cyc. App. Mech., vol. ii., and in Modern Mechanism.

**Cold Chisels.**—Angle of cutting-faces (Joshua Rose): For cast steel, about 65 degrees; for gun-metal or brass, about 50 degrees; for copper and soft metals, about 30 to 35 degrees.

**Rule for Gearing Lathes for Screw-cutting.** (Garvin Machine Co.)—Read from the lathe index the number of threads per inch cut by equal gears, and multiply it by any number that will give for a product a gear on the index; put this gear upon the stud, then multiply the number of threads per inch to be cut by the same number, and put the resulting gear upon the screw.

**EXAMPLE.**—To cut  $11\frac{1}{2}$  threads per inch. We find on the index that 48 into 48 cuts 6 threads per inch, then  $6 \times 4 = 24$ , gear on stud, and  $11\frac{1}{2} \times 4 = 46$ , gear on screw. Any multiplier may be used so long as the products include gears that belong with the lathe. For instance, instead of 4 as a multiplier we may use 6. Thus,  $6 \times 6 = 36$ , gear upon stud, and  $11\frac{1}{2} \times 6 = 69$ , gear upon screw.

**Rules for Calculating Simple and Compound Gearing where there is no Index.** (*Am Mach.*)—If the lathe is simple-gear, and the stud runs at the same speed as the spindle, select some gear for the screw, and multiply its number of teeth by the number of threads per inch in the lead-screw, and divide this result by the number of threads per inch to be cut. This will give the number of teeth in the gear for the stud. If this result is a fractional number, or a number which is not among the gears on hand, then try some other gear for the screw. Or, select the gear for the stud first, then multiply its number of teeth by the number of threads per inch to be cut, and divide by the number of threads per inch on the lead-screw. This will give the number of teeth for the gear on the screw. If the lathe is compound, select at random all the driving-gears, multiply the numbers of their teeth together, and this product by the number of threads to be cut. Then select at random all the driven gears except one; multiply the numbers of their teeth together, and this product by the number of threads per inch in the lead-screw. Now divide the first result by the second, to obtain the number of teeth in the remaining driven gear. Or, select at random all the driven gears. Multiply the numbers of their teeth together, and this product by the number of threads per inch in the lead-screw. Then select at random all the driving-gears except one. Multiply the numbers of their teeth together, and this result by the number of threads per inch of the screw to be cut. Divide the first result by the last, to obtain the number of teeth in the remaining driver. When the gears on the compounding stud are fast together, and cannot be changed, then the driven one has usually twice as many teeth as the other, or driver, in which case in the calculations consider the lead-screw to have twice as many threads per inch as it actually has, and then ignore the compounding entirely. Some lathes are so constructed that the stud on which the first driver is placed revolves only half as fast as the spindle. This can be ignored in the calculations by doubling the number of threads of the lead-screw. If both the last conditions are present ignore them in the calculations by multiplying the number of threads per inch in the lead-screw by four. If the thread to be cut is a fractional one, or if the pitch of the lead-screw is fractional, or if both are fractional, then reduce the fractions to a common denominator, and use the numerators of these fractions as if they equalled the pitch of the screw

to be cut, and of the lead-screw, respectively. Then use that part of the rule given above which applies to the lathe in question. For instance, suppose it is desired to cut a thread of 25/32-inch pitch, and the lead-screw has 4 threads per inch. Then the pitch of the lead-screw will be 1/4 inch, which is equal to 8/32 inch. We now have two fractions, 25/32 and 8/32, and the two screws will be in the proportion of 25 to 8, and the gears can be figured by the above rule, assuming the number of threads to be cut to be 8 per inch, and those on the lead-screw to be 25 per inch. But this latter number may be further modified by conditions named above, such as a reduced speed of the stud, or fixed compound gears. In the instance given, if the lead-screw had been 2 1/2 threads per inch, then its pitch being 4/10 inch, we have the fractions 4/10 and 25/32, which, reduced to a common denominator, are 64/160 and 125/160, and the gears will be the same as if the lead-screw had 125 threads per inch, and the screw to be cut 64 threads per inch.

On this subject consult also "Formulas in Gearing," published by Brown & Sharpe Mfg. Co., and Jamieson's Applied Mechanics.

**Change-gears for Screw-cutting Lathes.**—There is a lack of uniformity among lathe-builders as to the change-gears provided for screw-cutting. W. R. Macdonald, in *Am. Mach.*, April 7, 1892, proposes the following series, by which 33 whole threads (not fractional) may be cut by changes of only nine gears:

Screw.	Spindle.									Whole Threads.			
	20	30	40	50	60	70	110	120	130				
20	...	8	6	4 4/5	4	3 3/7	2 2/11	2	1 11/13	2	11	22	44
30	18	...	9	7 1/5	6	5 1/7	3 3/11	3	2 10/13	3	12	24	48
40	24	16	12	9 3/5	8	6 6/7	4 4/11	4	3 9/13	4	13	26	52
50	30	20	15	...	10	8 4/7	5 5/11	5	4 8/13	5	14	28	66
60	36	24	18	14 2/5	...	10 2/7	6 6/11	6	5 7/13	6	15	30	72
70	42	28	21	16 4/5	14	...	7 7/11	7	6 6/13	7	16	33	78
110	66	44	33	26 2/5	22	18 6/7	...	11	10 2/13	8	18	36	
120	72	48	36	28 4/5	24	20 4/7	13 1/11	...	11 1/13	9	20	39	
130	78	52	39	31 1/5	26	22 3/7	14 2/11	13	...	10	21	42	

Ten gears are sufficient to cut all the usual threads, with the exception of perhaps 11 1/2, the standard pipe-thread; in ordinary practice any fractional thread between 11 and 12 will be near enough for the customary short pipe-thread; if not, the addition of a single gear will give it.

In this table the pitch of the lead-screw is 12, and it may be objected to as too fine for the purpose. This may be rectified by making the real pitch 6 or any other desirable pitch, and establishing the proper ratio between the lathe spindle and the gear-stud.

**Metric Screw-threads** may be cut on lathes with inch-divided lead-screws, by the use of change wheels with 50 and 127 teeth; for 127 centimetres = 50 inches (127 x 0.3937 = 49.9999 in.).

**Rule for Setting the Taper in a Lathe.** (*Am. Mach.*)—No rule can be given which will produce exact results, owing to the fact that the centres enter the work an indefinite distance. If it were not for this circumstance the following would be an exact rule, and it is an approximation as it is. To find the distance to set the centre over: Divide the difference in the diameters of the large and small end of the taper by 2, and multiply this quotient by the ratio which the total length of the shaft bears to the length of the tapered portion. Example: Suppose a shaft three feet long is to have a taper turned on the end one foot long, the large end of the taper being two inches and the small end one inch diameter.  $\frac{2-1}{2} \times \frac{3}{1} = 1\frac{1}{2}$  inches.

**Electric Drilling-machines—Speed of Drilling Holes in Steel Plates.** (*Proc. Inst. M. E.*, Aug. 1887, p. 329.)—In drilling holes in the shell of the S.S. "Albania," after a very small amount of practice the men working the machines drilled the 7/8-inch holes in the shell with great rapidity, doing the work at the rate of one hole every 69 seconds, inclusive of the time occupied in altering the position of the machines by means of differential pulley-blocks, which were not conveniently arranged as slings for this purpose. Repeated trials of these drilling-machines have also shown that, when using electrical energy in both holding-on magnets and motor

amounting to about  $\frac{3}{4}$  H.P., they have drilled holes of 1 inch diameter through  $1\frac{1}{2}$  inch thickness of solid wrought iron, or through  $1\frac{5}{8}$  inch of mild steel in two plates of  $13/16$  inch each, taking exactly  $1\frac{3}{4}$  min. for each hole.

**Speed of Drills.** (Morse Twist-drill and Machine Company.)—The following table gives the revolutions per minute for drills from  $1/16$  in. to 2 in. diameter, as usually applied:

Diameter of Drills, in.	Speed for Wrought Iron and Steel.	Speed for Cast Iron.	Speed for Brass.	Diameter of Drills, in.	Speed for Wrought Iron and Steel.	Speed for Cast Iron.	Speed for Brass.
$1/16$	1712	2383	3544	$1\ 1/16$	72	108	180
$1/8$	855	1191	1772	$1\ 1/8$	68	102	170
$3/16$	571	794	1181	$1\ 3/16$	64	97	161
$1/4$	397	565	855	$1\ 1/4$	58	89	150
$5/16$	318	452	684	$1\ 5/16$	55	84	143
$3/8$	265	377	570	$1\ 3/8$	53	81	136
$7/16$	227	323	489	$1\ 7/16$	50	77	130

One inch to be drilled in soft cast iron will usually require: for  $1/4$ -in. drill, 160 revolutions; for  $1/2$ -in. drill, 140 revolutions; for  $3/4$ -in. drill, 100 revolutions; for 1-in. drill, 95 revolutions. These speeds should seldom be exceeded. Feed per revolution for  $1/4$ -in. drill, .005 inch; for  $1/2$ -in. drill, .007 inch; for  $3/4$ -in. drill .010 inch.

The rates of feed for twist drills are thus given by the same company:

Diameter of drill.....	$1/16$	$1/4$	$3/8$	$1/2$	$3/4$	1	$1\ 1/2$
Revs. per inch depth of hole.	125	125	120 to 140		1 inch feed per min.		

**MILLING-CUTTERS.**

George Addy, (Proc. Inst. M. E., Oct. 1890, p. 537), gives the following:

**Analyses of Steel.**—The following are analyses of milling-cutter blanks, made from best quality crucible cast steel and from self-hardening "Ivanhoe" steel:

	Crucible Cast Steel, per cent.	Ivanhoe Steel, per cent.
Carbon .....	1.2	1.67
Silicon .....	0.112	0.252
Phosphorus .....	0.018	0.051
Manganese .....	0.36	2.557
Sulphur .....	0.02	0.01
Tungsten .....	.....	4.65
Iron, by difference.....	98.29	90.81
	<u>100.000</u>	<u>100.000</u>

The first analysis is of a cutter 14 in. diam., 1 in. wide, which gave very good service at a cutting-speed of 60 ft. per min. Large milling-cutters are sometimes built up, the cutting-edges only being of tool steel. A cutter 22 in. diam. by  $5\frac{1}{2}$  in. wide has been made in this way, the teeth being clamped between two cast-iron flanges. Mr. Addy recommends for this form of tooth one with a cutting-angle of  $70^\circ$ , the face of the tooth being set  $10^\circ$  back of a radial line on the cutter, the clearance-angle being thus  $10^\circ$ . At the Clarence Iron-works, Leeds, the face of the tooth is set  $10^\circ$  back of the radial line for cutting wrought iron and  $20^\circ$  for steel.

**Pitch of Teeth.**—For obtaining a suitable pitch of teeth for milling-cutters of various diameters there exists no standard rule, the pitch being usually decided in an arbitrary manner according to individual taste.

For estimating the pitch of teeth in a cutter of any diameter from 4 in. to 15 in., Mr. Addy has worked out the following rule, which he has found capable of giving good results in practice:

$$\text{Pitch in inches} = \sqrt{(\text{diam. in inches} \times 8)} \times 0.0625 = .177 \sqrt{\text{diam.}}$$

J. M. Gray gives a rule for pitch as follows: The number of teeth in a milling-cutter ought to be 100 times the pitch in inches; that is, if there were 27 teeth, the pitch ought to be 0.27 in. The rules are practically the same, for if  $d = \text{diam.}$ ,  $n = \text{No. of teeth}$ ,  $p = \text{pitch}$ ,  $c = \text{circumference}$ ,  $c = pn$ ;  $d = \frac{pn}{\pi} = \frac{100p^2}{\pi} = 31.83p^2$ ;  $p = \sqrt{.0314d} = .177 \sqrt{d}$ ; No. of teeth,  $n = 3.14d \div p$ .

**Number of Teeth in Mills or Cutters.** (Joshua Rose.)—The teeth of cutters must obviously be spaced wide enough apart to admit of the emery-wheel grinding one tooth without touching the next one, and the front faces of the teeth are always made in the plane of a line radiating from the axis of the cutter. In cutters up to 3 in. in diam. it is good practice to provide 8 teeth per in. of diam., while in cutters above that diameter the spacing may be coarser, as follows:

Diameter of cutter, 6 in.;	number of teeth in cutter, 40
“ “ “ 7 “	“ “ “ “ 45
“ “ “ 8 “	“ “ “ “ 50

**Speed of Cutters.**—The cutting speed for milling was originally fixed very low; but experience has shown that with the improvements now in use it may with advantage be considerably increased, especially with cutters of large diameter. The following are recommended as safe speeds for cutters of 6 in. and upwards, provided there is not any great depth of material to cut away:

	Steel.	Wrought iron.	Cast iron.	Brass.
Feet per minute... ..	36	48	60	120
Feed, inch per min... ..	$\frac{1}{2}$	1	$1\frac{1}{2}$	$2\frac{1}{2}$

Should it be desired to remove any large quantity of material, the same cutting-speeds are still recommended, but with a finer feed. A simple rule for cutting-speed is: Number of revolutions per minute which the cutter spindle should make when working on cast iron = 240, divided by the diameter of the cutter in inches.

**Speed of Milling-cutters.** (Proc. Inst. M. E., April, 1883, p. 248.)—The cutting-speed which can be employed in milling is much greater than that which can be used in any of the ordinary operations of turning in the lathe, or of planing, shaping, or slotting. A milling-cutter with a plentiful supply of oil, or soap and water, can be run at from 80 to 100 ft. per min., when cutting wrought iron. The same metal can only be turned in a lathe, with a tool-holder having a good cutter, at the rate of 30 ft. per min., or at about one third the speed of milling. A milling-cutter will cut cast steel at the rate of 25 to 30 ft. per min.

The following extracts are taken from an article on speed and feed of milling-cutters in *Eng'g*, Oct. 22, 1891: Milling-cutters are successfully employed on cast iron at a speed of 250 ft. per min.; on wrought iron at from 80 ft. to 100 ft. per min. The latter materials need a copious supply of good lubricant, such as oil or soapy water. These rates of speed are not approached by other tools. The usual cutting-speeds on the lathe, planing, shaping, and slotting machines rarely exceed about one third of those given above, and frequently average about a fifth, the time lost in back strokes not being reckoned.

The feed in the direction of cutting is said by one writer to vary, in ordinary work, from 40 to 70 revs. of a 4-in. cutter per in. of feed. It must always to an extent depend on the character of the work done, but the above gives shavings of extreme thinness. For example, the circumference of a 4-in. cutter being, say,  $12\frac{1}{2}$  in., and having, say, 60 teeth, the advance corresponding to the passage of one cutting-tooth over the surface, in the coarser of the above-named feed-motions, is  $\frac{1}{40} \times \frac{1}{60} = \frac{1}{2400}$  in.; the finer feed gives an advance for each tooth of only  $\frac{1}{70} \times \frac{1}{60} = \frac{1}{4200}$  in. Such fine feeds as these are used only for light finishing cuts, and the same authority recommends, also for finishing, a cutter about 9 in. in circumference, or nearly 3 in. in diameter, which should be run at about 60 revs. per min. to cut tough wrought steel, 120 for ordinary cast iron, about 80 for wrought

iron, and from 140 to 160 for the various qualities of gun-metal and brass. With cutters smaller or larger the rates of revolution are increased or diminished to accord with the following table, which gives these rates of cutting-speeds and shows the lineal speed of the cutting-edge:

	Steel.	Wrought Iron.	Cast Iron.	Gun-metal.	Brass.
Feet per minute...	45	60	90	105	120

These speeds are intended for very light finishing cuts, and they must be reduced to about one half for heavy cutting.

The following results have been found to be the highest that could be attained in ordinary workshop routine, having due consideration to economy and the time taken to change and grind the cutters when they become dull: Wrought iron—36 ft. to 40 ft. per min.; depth of cut, 1 in.; feed,  $\frac{5}{8}$  in. per min. Soft mild steel—About 30 ft. per min.; depth of cut,  $\frac{1}{4}$  in.; feed,  $\frac{3}{4}$  in. per min. Tough gun-metal—80 ft. per min.; depth of cut,  $\frac{1}{2}$  in.; feed,  $\frac{3}{4}$  in. per min. Cast-iron gear-wheels— $26\frac{1}{2}$  ft. per min.; depth of cut,  $\frac{1}{2}$  in.; feed,  $\frac{3}{4}$  in. per min. Hard, close-grained cast iron—30 ft. per min.; depth of cut,  $2\frac{1}{2}$  in.; feed,  $\frac{5}{16}$  in. per min. Gun-metal joints, 53 ft. per min.; depth of cut,  $1\frac{3}{8}$  in.; feed,  $\frac{5}{8}$  in. per min. Steel-bars—21 ft. per min.; depth of cut,  $\frac{1}{32}$  in.; feed,  $\frac{3}{4}$  in. per min.

A stepped milling-cutter, 4 in. in diam. and 12 in. wide, tested under two conditions of speed in the same machine, gave the following results: The cutter in both instances was worked up to its maximum speed before it gave way, the object being to ascertain definitely the relative amount of work done by a high speed and a light feed, as compared with a low speed and a heavy cut. The machine was used single-gear and double-gear, and in both cases the width of cut was  $10\frac{1}{2}$  in.

Single-gear, 42 ft. per min.;  $\frac{5}{16}$  in. depth of cut; feed, 1.3 in. per min. = 4.16 cu. in. per min. Double-gear, 19 ft. per min.;  $\frac{3}{8}$  in. depth of cut; feed,  $\frac{5}{8}$  in. per min. = 2.40 cu. in. per min.

**Extreme Results with Milling-machines.**—Horace L. Arnold (*Am. Mach.*, Dec. 28, 1893) gives the following results in flat-surface milling, obtained in a Pratt & Whitney milling-machine: The mills for the flat cut were 5" diam., 12 teeth, 40 to 50 revs. and  $4\frac{7}{8}$ " feed per min. One single cut was run over this piece at a feed of 9" per min., but the mills showed plainly at the end that this rate was greater than they could endure. At 50 revs. for these mills the figures are as follows, with  $4\frac{7}{8}$ " feed: Surface speed, 64 ft., nearly; feed per tooth, 0.00812"; cuts per inch, 123. And with 9" feed per min.: Surface speed, 64 ft. per min.; feed per tooth, 0.015"; cuts per inch,  $66\frac{2}{3}$ .

At a feed of  $4\frac{7}{8}$ " per min. the mills stood up well in this job of cast-iron surfacing, while with a 9" feed they required grinding after surfacing one piece; in other words, it did not damage the mill-teeth to do this job with 123 cuts per in. of surface finished, but they would not endure  $66\frac{2}{3}$  cuts per inch. In this cast-iron milling the surface speed of the mills does not seem to be the factor of mill destruction: it is the increase of feed per tooth that prohibits increased production of finished surface. This is precisely the reverse of the action of single-pointed lathe and planer tools in general: with such tools there is a surface-speed limit which cannot be economically exceeded for dry cuts, and so long as this surface-speed limit is not reached, the cut per tooth or feed can be made anything up to the limit of the driving power of the lathe or planer, or to the safe strain on the work itself, which can in many cases be easily broken by a too great feed.

In wrought metal extreme figures were obtained in one experiment made in cutting keyways  $\frac{5}{16}$ " wide by  $\frac{1}{8}$ " deep in a bank of 8 shafts  $1\frac{1}{4}$ " diam. at once, on a Pratt & Whitney No. 3 column milling-machine. The 8 mills were successfully operated with 45 ft. surface speed and  $19\frac{1}{2}$  in. per min. feed; the cutters were 5" diam., with 28 teeth, giving the following figures, in steel: Surface speed, 45 ft. per min.; feed per tooth, 0.02024"; cuts per inch, 50, nearly. Fed with the revolution of mill. Flooded with oil, that is, a large stream of oil running constantly over each mill. Face of tooth radial. The resulting keyway was described as having a heavy wave or cutter-mark in the bottom, and it was said to have shown no signs of being heavy work on the cutters or on the machine. As a result of the experiment it was decided for economical steady work to run at 17 revs., with a feed of 4" per min., flooded cut, work fed with mill revolution, giving the following figures: Surface speed,  $22\frac{1}{4}$  ft. per min.; feed per tooth, 0.0084"; cuts per inch, 119.

An experiment in milling a wrought-iron connecting-rod of a locomotive on a Pratt & Whitney double-head milling-machine is described in the *Iron Age*, Aug. 27, 1891. The amount of metal removed at one cut measured  $3\frac{1}{2}$  in. wide by  $1\frac{3}{16}$  in. deep in the groove, and across the top  $\frac{1}{8}$  in. deep by  $4\frac{3}{4}$  in. wide. This represented a section of nearly  $4\frac{1}{2}$  sq. in. This was done at the rate of  $1\frac{3}{4}$  in. per min. Nearly 8 cu. in. of metal were cut up into chips every minute. The surface left by the cutter was very perfect. The cutter moved in a direction contrary to that of ordinary practice; that is, it cut down from the upper surface instead of up from the bottom.

**Milling "with" or "against" the Feed.**—Tests made with the Brown & Sharpe No. 5 milling-machine (described by H. L. Arnold, in *Am. Mach.*, Oct. 18, 1894) to determine the relative advantage of running the milling-cutter with or against the feed—"with the feed" meaning that the teeth of the cutter strike on the top surface or "scale" of cast-iron work in process of being milled, and "against the feed" meaning that the teeth begin to cut in the clean, newly cut surface of the work and cut upwards toward the scale—showed a decided advantage in favor of running the cutter against the feed. The result is directly opposite to that obtained in tests of a Pratt & Whitney machine, by experts of the P. & W. Co.

In the tests with the Brown & Sharpe machine the cutters used were 6 inches face by  $4\frac{1}{2}$  and 3 inches diameter respectively, 15 teeth in each mill, 42 revolutions per minute in each case, or nearly 50 feet per minute surface speed for the  $4\frac{1}{2}$ -inch and 33 feet per minute for the 3-inch mill. The revolution marks were 6 to the inch, giving a feed of 7 inches per minute, and a cut per tooth of .011". When the machine was forced to the limit of its driving the depth of cut was  $11/32$  inch when the cutter ran in the "old" way, or against the feed, and only  $\frac{1}{4}$  inch when it ran in the "new" way, or with the feed. The endurance of the milling-cutters was much greater when they were run in the "old" way.

**Spiral Milling-cutters.**—There is no rule for finding the angle of the spiral; from  $10^{\circ}$  to  $15^{\circ}$  is usually considered sufficient; if much greater the end thrust on the spindle will be increased to an extent not desirable for some machines.

**Milling-cutters with Inserted Teeth.**—When it is required to use milling-cutters of a greater diameter than about 8 in., it is preferable to insert the teeth in a disk or head, so as to avoid the expense of making solid cutters and the difficulty of hardening them, not merely because of the risk of breakage in hardening them, but also on account of the difficulty in obtaining a uniform degree of hardness or temper.

**Milling-machine versus Planer.**—For comparative data of work done by each see paper by J. J. Grant, *Trans. A. S. M. E.*, ix, 259. He says: The advantages of the milling machine over the planer are many, among which are the following: Exact duplication of work; rapidity of production—the cutting being continuous; cost of production, as several machines can be operated by one workman, and he not a skilled mechanic; and cost of tools for producing a given amount of work.

## POWER REQUIRED FOR MACHINE TOOLS.

**Resistance Overcome in Cutting Metal.** (*Trans. A. S. M. E.*, viii, 308.)—Some experiments made at the works of William Sellers & Co. showed that the resistance in cutting steel in a lathe would vary from 180,000 to 700,000 pounds per square inch of section removed, while for cast iron the resistance is about one third as much. The power required to remove a given amount of metal depends on the shape of the cut and on the shape and the sharpness of the tool used. If the cut is nearly square in section, the power required is a minimum; if wide and thin, a maximum. The dulness of a tool affects but little the power required for a heavy cut.

**Heavy Work on a Planer.**—Wm. Sellers & Co. write as follows to the *American Machinist*: The 120" planer table is geared to run 18 ft. per minute under cut, and 72 feet per minute on the return, which is equivalent, without allowance for time lost in reversing, to continuous cut of 14.4 feet per minute. Assuming the work to be 28 feet long, we may take 14 feet as the continuous cutting speed per minute, the .8 of a foot being much more than sufficient to cover time loss in reversing and feeding. The machine carries four tools. At  $\frac{1}{8}$ " feed per tool, the surface planed per hour would be 35 square feet. The section of metal cut at  $\frac{3}{4}$ " depth would be  $.75" \times .125" \times 4 = .375$  square inch, which would require approximately 30,000 lbs.

pressure to remove it. The weight of metal removed per hour would be  $14 \times 12 \times .375 \times .26 \times 60 = 1082.8$  lbs. Our earlier form of 36" planer has removed with one tool on  $\frac{3}{4}$ " cut on work 200 lbs. of metal per hour, and the 120" machine has more than five times its capacity. The total pulling power of the planer is 45,000 lbs.

**Horse-power Required to Run Lathes.** (J. J. Flather, *Am. Mach.*, April 23, 1891.)—The power required to do useful work varies with the depth and breadth of chip, with the shape of tool, and with the nature and density of metal operated upon; and the power required to run a machine empty is often a variable quantity.

For instance, when the machine is new, and the working parts have not become worn or fitted to each other as they will be after running a few months, the power required will be greater than will be the case after the running parts have become better fitted.

Another cause of variation of the power absorbed is the driving-belt; a tight belt will increase the friction, hence to obtain the greatest efficiency of a machine we should use wide belts, and run them just tight enough to prevent slip. The belts should also be soft and pliable, otherwise power is consumed in bending them to the curvature of the pulleys.

A third cause is the variation of journal-friction, due to slacking up or tightening the cap-screws, and also the end-thrust bearing screw.

Hartig's investigations show that it requires less total power to turn off a given weight of metal in a given time than it does to plane off the same amount; and also that the power is less for large than for small diameters.

The following table gives the actual horse-power required to drive a lathe empty at varying numbers of revolutions of main spindle.

HORSE-POWER FOR SMALL LATHES.

Without Back Gears.		With Back Gears.		Remarks.
Revs. of Spindle per min.	H.P. required to drive empty.	Revs. of Spindle per min.	H.P. required to drive empty.	
132.72	.145	14.6	.126	20" Fitchburg lathe.
219.08	.197	24.33	.141	
365.00	.310	38.42	.274	
47.4	.159	4.84	.132	Small lathe (13½"), Chemnitz, Germany. New machine.
125.0	.259	12.8	.187	
188	.339	19.2	.230	
54.6	.206	6.61	.157	17½" lathe do. New machine.
122	.339	14.8	.206	
183	.455	22.1	.249	
18.8	.086	2.31	.035	26" lathe do.
54.6	.210	6.72	.063	
82.2	.326	10.8	.087	

If  $H.P._0$  = horse-power necessary to drive lathe empty, and  $N$  = number of revolutions per minute, then the equation for average small lathes is  $H.P._0 = 0.095 + 0.0012N$ .

For the power necessary to drive the lathes empty when the back gears are in, an average equation for lathes under 20" swing is

$$H.P._0 = 0.10 + 0.006N.$$

The larger lathes vary so much in construction and detail that no general rule can be obtained which will give, even approximately, the power required to run them, and although the average formula shows that at least 0.095 horse-power is needed to start the small lathes, there are many American lathes under 20" swing working on a consumption of less than 0.5 horse-power.

The amount of power required to remove metal in a machine is determinable within more accurate limits.

Referring to Dr. Hartig's researches,  $H.P._1 = CW$ , where  $C$  is a constant, and  $W$  the weight of chips removed per hour.

Average values of  $C$  are .030 for cast-iron, .032 for wrought-iron, .047 for steel.

The size of lathe, and, therefore, the diameter of work, has no apparent effect on the cutting power. If the lathe be heavy, the cut can be increased, and consequently the weight of chips increased, but the value of  $C$  appears to be about the same for a given metal through several varying sizes of lathes.

HORSE-POWER REQUIRED TO REMOVE CAST IRON IN A 20-INCH LATHE.  
(J. J. Hobart.)

Descriptive No.	Number of Trials.	Tool used.	Average Cutting-speed in feet per minute.	Depth of Cut in inches.	Average Breadth of Cut in inches.	Average H.P. required to remove Metal.	Average pounds Metal turned off per hour.	Value of Constant $C$ .
1	22	Side tool.....	37.90	.125	.015	.342	13.30	.025
2	15	Diamond.....	30.50	.125	.015	.218	10.70	.020
3	17	Round nose.....	42.61	.125	.015	.352	14.95	.023
4	2	Left-hand round nose.....	26.29	.125	.015	.237	9.22	.026
5	4	Square-faced tool $\frac{1}{2}$ " broad.....	25.82	.015	.125	.255	9.06	.028
6	1	"	25.27	.048	.048	.200	10.89	.018
7	1	"	25.64	.125	.015	.246	8.99	.027

The above table shows that an average of .26 horse-power is required to turn off 10 pounds of cast-iron per hour, from which we obtain the average value of the constant  $C = .024$ .

Most of the cuts were taken so that the metal would be reduced  $\frac{1}{4}$ " in diameter; with a broad surface cut and a coarse feed, as in No. 5, the power required per pound of chips removed in a given time was a maximum; the least power per unit of weight removed being required when the chip was square, as in No. 6.

HORSE-POWER REQUIRED TO REMOVE METAL IN A 29-INCH LATHE.  
(R. H. Smith.)

Number of Experiments.	Metal.	Cutting-speed, ft. per min.	Depth of Cut, in.	Average Breadth of Cut, in.	Average H.P. required to remove Metal.	Average pounds Metal removed per hour.	Value of $C$ .
4	Cast iron	12.7	.05	.046	.105	5.49	.019
4	Cast iron	11.1	.135	.046	.217	12.96	.017
4	Cast iron	12.85	.04	.038	.093	3.66	.027
4	Wrought iron	9.6	.03	.046	.059	2.49	.023
4	Wrought iron	9.1	.06	.046	.138	4.72	.029
4	Wrought iron	9.9	.14	.046	.186	9.56	.019
4	Wrought iron	9.35	.045	.038	.092	2.99	.031
4	Steel	6.00	.02	.046	.043	1.03	.042
4	Steel	5.8	.04	.046	.085	2.00	.042
4	Steel	5.1	.06	.046	.108	2.64	.040

The small values of  $C$ , .017 and .019, obtained for cast iron are probably due to two reasons: the iron was soft and of fine quality, known as pulley metal, requiring less power to cut; and, as Prof. Smith remarks, a lower cutting-speed also takes less horse-power.

Hardness of metals and forms of tools vary, otherwise the amount of chips turned out per hour per horse-power would be practically constant, the higher cutting-speeds decreasing but slightly the visible work done.

Taking into account these variations, the weight of metal removed per hour, multiplied by a certain constant, is equal to the power necessary to do the work.

This constant, according to the above tests, is as follows:

	Cast Iron.	Wrought Iron.	Steel.
Hartig.....	.030	.032	.047
Smith.....	.023	.028	.042
Hobart.....	.024		
Average.....	.026	.030	.044

The power necessary to run the lathe empty will vary from about .05 to .5 H.P., which should be ascertained and added to the useful horse-power, to obtain the total power expended.

**Power used by Machine-tools.** (R. E. Dinsmore, from the *Electrical World*.)

1. Shop shafting 2 3/16" × 180 ft. at 160 revs., carrying 2" pulleys from 6" diam. to 36", and running 20 idle machine belt ..... 1.32 H.P.
2. Lodge-Davis upright back-gear drill-press with table, 28" swing, drilling 3/8" hole in cast iron, with a feed of 1 in. per minute..... 0.78 H.P.
3. Morse twist-drill grinder No. 2, carrying 2' × 6" wheels at 3200 revs..... 0.29 H.P.

9. Heavy planer 28" × 28" × 14 ft. bed, stroke 8", cutting steel, 22 reversals per minute. .... 3.2 H.P.

The table on the next page compiled from various sources, principally from Hartig's researches, by Prof. J. J. Flather (*Am. Mach.*, April 12, 1894), may be used as a guide in estimating the power required to run a given machine; but it must be understood that these values, although determined by dynamometric measurements for the individual machines designated, are not necessarily representative, as the power required to drive a machine itself is dependent largely on its particular design and construction. The character of the work to be done may also affect the power required to operate; thus a machine to be used exclusively for brass work may be speeded from 10% to 15% higher than if it were to be used for iron work of similar size, and the power required will be proportionately greater.

Where power is to be transmitted to the machines by means of shafting and countershafts, an additional amount, varying from 30% to 50% of the total power absorbed by the machines, will be necessary to overcome the friction of the shafting.

**Horse-power required to drive Shafting.**—Samuel Webber, in his "Manual of Power" gives among numerous tables of power required to drive textile machinery, a table of results of tests of shafting. A line of 2 1/8" shafting, 342 ft. long, weighing 4098 lbs., with pulleys weighing 5331 lbs., or a total of 9429 lbs., supported on 47 bearings, 216 revolutions per minute, required 1.858 H.P. to drive it. This gives a coefficient of friction of 5.52%. In seventeen tests the coefficient ranged from 3.34% to 11.4%, averaging 5.73%.

**Horse-power consumed in Machine-shops.**—How much power is required to drive ordinary machine-tools? and how many men can be employed per horse-power? are questions which it is impossible to answer by any fixed rule. The power varies greatly according to the conditions in each shop. The following table given by J. J. Flather in his work on Dynamometers gives an idea of the variation in several large works. The percentage of the total power required to drive the shafting varies from 15 to 80, and the number of men employed per total H.P. varies from 0.62 to 6.04.

Abbreviations: E., engine; W.W., wood-working machinery; M. M., mining machinery; M. E., marine engines; L., locomotives; H. M., heavy machinery; M. T., machine tools; C. & L., cranes and locks; P. & D., presses and dies; P. & S., pulleys and shafting; H. F., heavy forgings; S. M., sewing-machines; M. S., machine-screws; F., files.

J. T. Henthorn states (Trans. A. S. M. E., vi. 462) that in print-mills which he examined the friction of the shafting and engine was in 7 cases below 20% and in 35 cases between 20% and 30%, in 11 cases from 30% to 35% and in 2 cases above 35%, the average being 25.9%. Mr. Barrus in eight cotton-mills found the range to be between 18% and 25.7%, the average being 22%. Mr. Flather believes that for shops using heavy machinery the percentage of power required to drive the shafting will average from 40% to 50% of the total power expended. This presupposes that under the head of shafting are included elevators, fans, and blowers.

**ABRASIVE PROCESSES.**

Abrasive cutting is performed by means of stones, sand, emery, glass, corundum, carborundum, crocus, rouge, chilled globules of iron, and in some cases by soft, friable iron alone. (See paper by John Richards, read before the Technical Society of the Pacific Coast, *Am. Mach.*, Aug. 20, 1891, and *Eng. & M. Jour.*, July 25 and Aug. 15, 1891.)

**The "Cold Saw."**—For sawing any section of iron while cold the cold saw is sometimes used. This consists simply of a plain soft steel or iron disk without teeth, about 42 inches diameter and  $\frac{3}{16}$  inch thick. The velocity of the circumference is about 15,000 feet per minute. One of these saws will saw through an ordinary steel rail cold in about one minute. In this saw the steel or iron is ground off by the friction of the disk, and is not cut as with the teeth of an ordinary saw. It has generally been found more profitable, however, to saw iron with disks or band-saws fitted with cutting-teeth, which run at moderate speeds, and cut the metal as do the teeth of a milling-cutter.

**Reese's Fusing-disk.**—Reese's fusing-disk is an application of the cold saw to cutting iron or steel in the form of bars, tubes, cylinders, etc., in which the piece to be cut is made to revolve at a slower rate of speed than the saw. By this means only a small surface of the bar to be cut is presented at a time to the circumference of the saw. The saw is about the same size as the cold saw above described, and is rotated at a velocity of about 25,000 feet per minute. The heat generated by the friction of this saw against the small surface of the bar rotated against it is so great that the particles of iron or steel in the bar are actually fused, and the "sawdust" welds as it falls into a solid mass. This disk will cut either cast iron, wrought iron, or steel. It will cut a bar of steel  $1\frac{3}{8}$  inch diameter in one minute, including the time of setting it in the machine, the bar being rotated about 200 turns per minute.

**Cutting Stone with Wire.**—A plan of cutting stone by means of a wire cord has been tried in Europe. While retaining sand as the cutting agent, M. Paulin Gay, of Marseilles, has succeeded in applying it by mechanical means, and as continuously as formerly the sand-blast and band-saw, with both of which appliances his system—that of the "helicoidal wire cord"—has considerable analogy. An engine puts in motion a continuous wire cord (varying from five to seven thirty-seconds of an inch in diameter, according to the work), composed of three mild-steel wires twisted at a certain pitch, that is found to give the best results in practice, at a speed of from 15 to 17 feet per second.

**The Sand-blast.**—In the sand-blast, invented by B. F. Tilghman, of Philadelphia, and first exhibited at the American Institute Fair, New York, in 1871, common sand, powdered quartz, emery, or any sharp cutting material is blown by a jet of air or steam on glass, metal, or other comparatively brittle substance, by which means the latter is cut, drilled, or engraved. To protect those portions of the surface which it is desired shall not be abraded it is only necessary to cover them with a soft or tough material, such as lead, rubber, leather, paper, wax, or rubber-paint. (See description in *App. Cyc. Mech.*; also U. S. report of Vienna Exhibition, 1873, vol. iii. 316.)

A "jet of sand" impelled by steam of moderate pressure, or even by the blast of an ordinary fan, depolishes glass in a few seconds; wood is cut quite rapidly; and metals are given the so-called "frosted" surface with great rapidity. With a jet issuing from under 300 pounds pressure, a hole was cut through a piece of corundrum  $1\frac{1}{2}$  inches thick in 25 minutes.

The sand-blast has been applied to the cleaning of metal castings and sheet metal, the graining of zinc plates for lithographic purposes, the frosting of silverware, the cutting of figures on stone and glass, and the cutting of devices on monuments or tombstones, the recutting of files, etc. The time required to sharpen a worn-out 14-inch bastard file is about four minutes. About one pint of sand, passed through a No. 120 sieve, and four horse-power of 60-lb. steam are required for the operation. For cleaning castings compressed air at from 8 to 10 pounds pressure per square inch is employed. Chilled-iron globules instead of quartz or flint-sand are used with good results, both as to speed of working and cost of material, when the operation can be carried on under proper conditions. With the expenditure of 2 horse-power in compressing air, 2 square feet of ordinary scale on the surface of steel and iron plates can be removed per minute. The surface thus prepared is ready for tinning, galvanizing, plating, bronzing, painting, etc. By continuing the operation the hard skin on the surface of castings, which is so destructive to the cutting edges of milling and other tools, can be removed. Small castings are placed in a sort of slowly rotating barrel, open at one or both ends, through which the blast is directed downward against them as they tumble over and over. No portion of the surface escapes the action of the sand. Plain cored work, such as valve-bodies, can be cleaned perfectly both inside and out. 100 lbs. of castings can be cleaned in from 10 to 15 minutes with a blast created by 2 horse-

power. The same weight of small forgings and stampings can be scaled in from 20 to 30 minutes.—*Iron Age*, March 8, 1894.

**EMERY-WHEELS AND GRINDSTONES.**

**The Selection of Emery-wheels.**—A pamphlet entitled “Emery-wheels, their Selection and Use,” published by the Brown & Sharpe Mfg. Co., after calling attention to the fact that too much should not be expected of one wheel, and commenting upon the importance of selecting the proper wheel for the work to be done, says :

Wheels are numbered from coarse to fine; that is, a wheel made of No. 60 emery is coarser than one made of No. 100. Within certain limits, and other things being equal, a coarse wheel is less liable to change the temperature of the work and less liable to glaze than a fine wheel. As a rule, the harder the stock the coarser the wheel required to produce a given finish. For example, coarser wheels are required to produce a given surface upon hardened steel than upon soft steel, while finer wheels are required to produce this surface upon brass or copper than upon either hardened or soft steel.

Wheels are graded from soft to hard, and the grade is denoted by the letters of the alphabet, A denoting the softest grade. A wheel is soft or hard chiefly on account of the amount and character of the material combined in its manufacture with emery or corundum. But other characteristics being equal, a wheel that is composed of fine emery is more compact and harder than one made of coarser emery. For instance, a wheel of No. 100 emery, grade B, will be harder than one of No. 60 emery, same grade.

The softness of a wheel is generally its most important characteristic. A soft wheel is less apt to cause a change of temperature in the work, or to become glazed, than a harder one. It is best for grinding hardened steel, cast-iron, brass, copper, and rubber, while a harder or more compact wheel is better for grinding soft steel and wrought iron. As a rule, other things being equal, the harder the stock the softer the wheel required to produce a given finish.

Generally speaking, a wheel should be softer as the surface in contact with the work is increased. For example, a wheel 1/16-inch face should be harder than one 1/2-inch face. If a wheel is hard and heats or chatters, it can often be made somewhat more effective by turning off a part of its cutting surface; but it should be clearly understood that while this will sometimes prevent a hard wheel from heating or chattering the work, such a wheel will not prove as economical as one of the full width and proper grade, for it should be borne in mind that the grade should always bear the proper relation to the width. (See the pamphlet referred to for other information. See also lecture by T. Dunkin Paret, Pres't of The Tanite Co., on Emery-wheels. Jour. Frank. Inst., March, 1890.)

**Speed of Emery-wheels.**—The following speeds are recommended by different makers :

Diameter of Wheel, inches	Revolutions per minute.				Diameter of Wheel, inches.	Revolutions per minute.			
	Waltham E. W. Co.	The Tanite Co.	Grant Corundum Wheel Co.	Norton E. W. Co		Waltham E. W. Co.	The Tanite Co.	Grant Corundum Wheel Co.	Norton E. W. Co.

9	2,150	2,400	2,400	2,450	36	550	611	400	550

“We advise the regular speed of 5500 feet per minute.” (Detroit Emery-wheel Co.)

“Experience has demonstrated that there is no advantage in running

solid emery-wheels at a higher rate than 5500 feet per minute peripheral speed." (Springfield E. W. Mfg. Co.)

"Although there is no exactly defined limit at which a wheel must be run to render it effective, experience has demonstrated that, taking into account safety, durability, and liability to heat, 5500 feet per minute at the periphery gives the best results. All first-class wheels have the number of revolutions necessary to give this rate marked on their labels, and a column of figures in the price-list gives a corresponding rate. Above this speed all wheels are unsafe. If run much below it they wear away rapidly in proportion to what they accomplish." (Northampton E. W. Co.)

**Grades of Emery.**—The numbers representing the grades of emery run from 8 to 120, and the degree of smoothness of surface they leave may be compared to that left by files as follows:

8 and 10	represent the cut of a wood rasp.
16 " 20	" " " " a coarse rough file.
24 " 30	" " " " an ordinary rough file.
36 " 40	" " " " a bastard file.
46 " 60	" " " " a second-cut file.
70 " 80	" " " " a smooth "
90 " 100	" " " " a superfine "
120 F and FF	" " " " a dead-smooth file.

**Speed of Polishing-wheels.**

Wood covered with leather, about.....	7000 ft. per minute
" " " a hair brush, about.....	2500 revs. for largest
" " 1½" to 8" diam., hair 1" to 1¼" long, ab.	4500 " " smallest
Walrus-hide wheels, about.....	8000 ft. per minute
Rag-wheels, 4 to 8 in. diameter, about.....	7000 " " "

**Safe Speeds for Grindstones and Emery-wheels.**—G. D. Hiscox (*Iron Age*, April 7, 1892), by an application of the formula for centrifugal force in fly-wheels (see Fly-wheels), obtains the figures for strains in grindstones and emery-wheels which are given in the tables below. His formulæ are:

Stress per sq. in. of section of a grindstone =  $(.7071D \times N)^2 \times .0000795$   
 " " " " " " " " an emery-wheel =  $(.7071D \times N)^2 \times .00010226$

*D* = diameter in feet, *N* = revolutions per minute.

He takes the weight of sandstone at .078 lb. per cubic inch, and that of an emery-wheel at 0.1 lb. per cubic inch; Ohio stone weighs about .081 lb. and Huron stone about .089 lb. per cubic inch. The Ohio stone will bear a speed at the periphery of 2500 to 3000 ft. per min., which latter should never be exceeded. The Huron stone can be trusted up to 4000 ft., when properly clamped between flanges and not excessively wedged in setting. Apart from the speed of grindstones as a cause of bursting, probably the majority of accidents have really been caused by wedging them on the shaft and over-wedging to true them. The holes being square, the excessive driving of wedges to true the stones starts cracks in the corners that eventually run out until the centrifugal strain becomes greater than the tenacity of the remaining solid stone. Hence the necessity of great caution in the use of wedges, as well as the holding of large quick-running stones between large flanges and leather washers.

**Strains in Grindstones.**

LIMIT OF VELOCITY AND APPROXIMATE ACTUAL STRAIN PER SQUARE INCH OF SECTIONAL AREA FOR GRINDSTONES OF MEDIUM TENSILE STRENGTH.

Diameter.	Revolutions per minute.						
	100	150	200	250	300	350	400
feet.	lbs.	lbs.	lbs.	lbs.	lbs.	lbs.	lbs.

4	6.35	14.30	27.37	.....	.....	.....	.....
4½	8.04	18.08	32.16	.....	.....	.....	.....
5	9.93	22.34	.....	.....	.....	.....	.....
6	14.30	32.17	.....	.....	.....	.....	.....
7	19.44	.....	.....	.....	.....	.....	.....

Approximate breaking strain ten times the strain for size opposite the bottom figure in each column.

Columns 3, 4, and 5 are given to show that if we start an 8-foot stone with, say, a countershaft pulley driving a 40-inch pulley on the grindstone spindle, and the stone makes the right number (135) of revolutions per minute, the reduction in the diameter of the pulley on the grinding-stone spindle, when the stone has been reduced 6 inches in diameter, will require to be also reduced  $2\frac{1}{2}$  inches in diameter, or to shift from 40 inches to  $37\frac{1}{2}$  inches, and so on similarly for columns 4 and 5. Any other suitable dimensions of pulley may be used for the stone when eight feet in diameter, but the number of inches in each shift named, in order to be correct, will have to be proportional to the numbers of revolutions the stone should run, as given in column 2 of the table.

**Varieties of Grindstones.**

The Morse Twist Drill and Machine Co. gives the following table showing the different sizes of drills that should be used when a suitable thread is to be tapped in a hole. The sizes given are practically correct.

**TAPER BOLTS, PINS, REAMERS, ETC.**

**Taper Bolts for Locomotives.**—Bolt-threads, U. S. standard, except stay-bolts and boiler-studs, V threads, 12 per inch; valves, cocks, and plugs, V threads, 14 per inch, and 1/8-inch taper per 1 inch. Standard bolt taper 1/16 inch per foot.

**Taper Reamers.**—The Pratt & Whitney Co. makes standard taper reamers for locomotive work taper 1/16 inch per foot from 1/4 inch diam.; 4 in. length of flute to 2 in. diam.; 18 in. length of flute, diameters advancing by 16ths and 32ds. P. & W. Co.'s standard taper pin reamers taper 1/4 in. per foot, are made in 14 sizes of diameters, 0.135 to 1.009 in.; length of flute 1 5/16 in. to 12 in.

DIMENSIONS OF THE PRATT & WHITNEY COMPANY'S REAMERS FOR MORSE STANDARD-TAPER SOCKET.

No.	Diameter Small End, inches.	Diameter Large End, inches.	Gauge Diam., large end, inches	Gauge L'ngth, inches.	Length Flute, inches.	Total L'ngth.	Taper per foot, inches.
1	0.365	0.525	0.475	2 1/8	3	5 1/4	0.600
2	0.573	0.749	0.699	2 1/2	3 1/2	6 1/4	0.602
3	0.779	0.982	0.936	3 5/16	4	7 1/2	0.602

**Standard Steel Taper-pins.**—The following sizes are made by The Pratt & Whitney Co.:

Number:	0	1	2	3	4	5	6	7	8	9	10
Diameter large end:	.156	.172	.193	.219	.250	.289	.341	.409	.492	.591	.706
Approximate fractional sizes:	5/32	11/64	3/16	7/32	1/4	19/64	11/32	13/32	1/2	19/32	23/32
Lengths from	3/4	3/4	3/4	3/4	3/4	3/4	3/4	1	1 1/4	1 1/2	1 3/4
To*	1	1 1/4	1 1/2	1 3/4	2	2 1/4	3 1/4	3 3/4	4 1/2	5 1/4	6
Diameter small end of standard taper-pin reamer:†	.135	.146	.162	.183	.208	.240	.279	.331	.398	.482	.581

**Standard Steel Mandrels.** (The Pratt & Whitney Co.)—These mandrels are made of tool-steel, hardened, and ground true on their centres. Centres are also ground to true 60° cones. The ends are of a form best adapted to resist injury likely to be caused by driving. They are slightly taper. Sizes, 1/4 in. diameter by 3 7/8 in. long to 2 in. diam. by 14 5/8 in. long, diameters advancing by 16ths.

**PUNCHES AND DIES, PRESSES, ETC.**

**Clearance between Punch and Die.**—For computing the amount of clearance that a die should have, or, in other words, the difference in size between die and punch, the general rule is to make the diameter of die-hole equal to the diameter of the punch, plus 2/10 the thickness of the plate. Or,  $D = d + .2t$ , in which  $D$  = diameter of die-hole,  $d$  = diameter of punch, and  $t$  = thickness of plate. For very thick plates some mechanics prefer to make the die-hole a little smaller than called for by the above rule. For ordinary boiler-work the die is made from 1/10 to 3/10 of the thickness of the plate larger than the diameter of the punch; and some boiler-makers advocate making the punch fit the die accurately. For punching nuts, the punch fits in the die. (*Am. Machinist.*)

**Kennedy's Spiral Punch.** (The Pratt & Whitney Co.)—B. Martell, Chief Surveyor of Lloyd's Register, reported tests of Kennedy's spiral punches in which a 7/8-inch spiral punch penetrated a 5/8-inch plate at a pressure of 22 to 25 tons, while a flat punch required 33 to 35 tons. Steel boiler-plates punched with a flat punch gave an average tensile strength of 58,579

\* Lengths vary by 1/4" each size. † Taken 1/2" from extreme end. Each size overlaps smaller one about 1/2". Taper 1/4" to the foot.

lbs. per square inch, and an elongation in two inches across the hole of 5.2%, while plates punched with a spiral punch gave 63,929 lbs., and 10.6% elongation.

The spiral shear form is not recommended for punches for use in metal of a thickness greater than the diameter of the punch. This form is of greatest benefit when the thickness of metal worked is less than two thirds the diameter of punch.

**Size of Blanks used in the Drawing-press.** Oberlin Smith (Jour. Frank. Inst., Nov. 1886) gives three methods of finding the size of blanks. The first is a tentative method, and consists simply in a series of experiments with various blanks, until the proper one is found. This is for use mainly in complicated cases, and when the cutting portions of the die and punch can be finally sized after the other work is done. The second method is by weighing the sample piece, and then, knowing the weight of the sheet metal per square inch, computing the diameter of a piece having the required area to equal the sample in weight. The third method is by computation, and the formula is  $x = \sqrt{d^2 + 4dh}$  for sharp-cornered cup, where  $x$  = diameter of blank,  $d$  = diameter of cup,  $h$  = height of cup. For round-cornered cup where the corner is small, say radius of corner less than  $\frac{1}{4}$  height of cup, the formula is  $x = (\sqrt{d^2 + 4dh}) - r$ , about;  $r$  being the radius of the corner. This is based upon the assumption that the thickness of the metal is not to be altered by the drawing operation.

**Pressure attainable by the Use of the Drop-press.** (R. H. Thurston, Trans. A. S. M. E., v. 53.)—A set of copper cylinders was prepared, of pure Lake Superior copper; they were subjected to the action of presses of different weights and of different heights of fall. Companion specimens of copper were compressed to exactly the same amount, and measures were obtained of the loads producing compression, and of the amount of work done in producing the compression by the drop. Comparing one with the other it was found that the work done with the hammer was 90% of the work which should have been done with perfect efficiency. That is to say, the work done in the testing-machine was equal to 90% of that due the weight of the drop falling the given distance.

Formula: Mean pressure in pounds =  $\frac{\text{Weight of drop} \times \text{fall} \times \text{efficiency}}{\text{compression}}$ .

For pressures per square inch, divide by the mean area opposed to crushing action during the operation.

**Flow of Metals.** (David Townsend, Jour. Frank. Inst., March, 1878.)—In punching holes  $\frac{7}{16}$  inch diameter through iron blocks  $1\frac{3}{4}$  inches thick, it was found that the core punched out was only  $1\frac{1}{16}$  inch thick, and its volume was only about 32% of the volume of the hole. Therefore, 68% of the metal displaced by punching the hole flowed into the block itself, increasing its dimensions.

## FORCING AND SHRINKING FITS.

### Forcing Fits of Pins and Axles by Hydraulic Pressure.

—A 4-inch axle is turned .015 inch diameter larger than the hole into which it is to be fitted. They are pressed on by a pressure of 30 to 35 tons. (Lecture by Coleman Sellers, 1872.)

For forcing the crank-pin into a locomotive driving-wheel, when the pin-hole is perfectly true and smooth, the pin should be pressed in with a pressure of 6 tons for every inch of diameter of the wheel fit. When the hole is not perfectly true, which may be the result of shrinking the tire on the wheel centre after the hole for the crank-pin has been bored, or if the hole is not perfectly smooth, the pressure may have to be increased to 9 tons for every inch of diameter of the wheel-fit. (*Am. Machinist.*)

**Shrinkage Fits.**—In 1886 the American Railway Master Mechanics' Association recommended the following shrinkage allowances for tires of standard locomotives. The tires are uniformly heated by gas-flames, slipped over the cast-iron centres, and allowed to cool. The centres are turned to the standard sizes given below, and the tires are bored smaller by the amount of the shrinkage designated for each:

Diameter of centre, in. . . . .	38	44	50	56	62	66
Shrinkage allowance, in. . . . .	.040	.047	.053	.060	.066	.070

This shrinkage allowance is approximately  $\frac{1}{80}$  inch per foot, or  $\frac{1}{960}$ . A common allowance is  $\frac{1}{1000}$ . Taking the modulus of elasticity of steel at

30,000,000, the strain caused by shrinkage would be 30,000 lbs. per square inch, less an uncertain amount due to compression of the centre.

**SCREWS, SCREW-THREADS, ETC.\***

**Efficiency of a Screw.**—Let  $a$  = angle of the thread, that is, the angle whose tangent is the pitch of the screw divided by the circumference of a circle whose diameter is the mean of the diameters at the top and bottom of the thread. Then for a square thread

$$\text{Efficiency} = \frac{1 - f \tan a}{1 + f \cotan a}$$

in which  $f$  is the coefficient of friction. (For demonstration, see Cotterill and Slade, Applied Mechanics, p. 146.) Since  $\cotan = 1 \div \tan$ , we may substitute for  $\cotan a$  the reciprocal of the tangent, or if  $p$  = pitch, and  $c$  = mean circumference of the screw,

$$\text{Efficiency} = \frac{1 - f \frac{p}{c}}{1 + f \frac{c}{p}}$$

**EXAMPLE.**—Efficiency of square-threaded screws of  $\frac{1}{2}$  in. pitch.

Diameter at bottom of thread, in....	1	2	3	4
“ “ top “ “ “....	$1\frac{1}{2}$	$2\frac{1}{2}$	$3\frac{1}{2}$	$4\frac{1}{2}$
Mean circumference “ “ “....	3.927	7.069	10.21	13.35
Cotaugent $a = c \div p$ .....	7.854	14.14	20.42	26.70
Tangent $a = p \div c$ .....	.1273	.0707	.0490	.0375
Efficiency if $f = .10$ .....	55.3%	41.2%	32.7%	27.2%
“ “ $f = .15$ .....	45%	31.7%	24.4%	19.9%

The efficiency thus increases with the steepness of the pitch.

The above formulæ and examples are for square-threaded screws, and consider the friction of the screw-thread only, and not the friction of the collar or step by which end thrust is resisted, and which further reduces the efficiency. The efficiency is also further reduced by giving an inclination to the side of the thread, as in the V-threaded screw. For discussion of this subject, see paper by Wilfred Lewis, Jour. Frank. Inst. 1880; also Trans. A. S. M. E., vol. xii. 784.

**Efficiency of Screw-bolts.**—Mr. Lewis gives the following approximate formula for ordinary screw-bolts (V threads, with collars):  $p$  = pitch of screw,  $d$  = outside diameter of screw,  $F$  = force applied at circumference to lift a unit of weight,  $E$  = efficiency of screw. For an average case, in which the coefficient of friction may be assumed at .15,

$$F = \frac{p + d}{3d}, \quad E = \frac{p}{p + d}$$

For bolts of the dimensions given above,  $\frac{1}{2}$ -in. pitch, and outside diameters  $1\frac{1}{2}$ ,  $2\frac{1}{2}$ ,  $3\frac{1}{2}$ , and  $4\frac{1}{2}$  in., the efficiencies according to this formula would be, respectively, .25, .167, .125, and .10.

James McBride (Trans. A. S. M. E., xii. 781) describes an experiment with an ordinary 2-in. screw-bolt, with a V thread,  $4\frac{1}{2}$  threads per inch, raising a weight of 7500 lbs., the force being applied by turning the nut. Of the power applied 89.8% was absorbed by friction of the nut on its supporting washer and of the threads of the bolt in the nut. The nut was not faced, and had the flat side to the washer.

Prof. Ball in his "Experimental Mechanics" says: "Experiments showed in two cases respectively about  $\frac{2}{3}$  and  $\frac{3}{4}$  of the power was lost."

Trautwine says: "In practice the friction of the screw (which under heavy loads becomes very great) make the theoretical calculations of but little value."

Weisbach says: "The efficiency is from 19% to 30%."

**Efficiency of a Differential Screw.**—A correspondent of the *American Machinist* describes an experiment with a differential screw-punch, consisting of an outer screw 2 in. diam., 3 threads per in., and an inner screw  $1\frac{3}{8}$  in. diam.,  $3\frac{1}{2}$  threads per inch. The pitch of the outer screw

\* For U. S. Standard Screw-threads, see page 204.

being  $\frac{1}{8}$  in. and that of the inner screw  $\frac{2}{7}$  in., the punch would advance in one revolution  $\frac{1}{8} - \frac{2}{7} = \frac{1}{21}$  in. Experiments were made to determine the force required to punch an  $\frac{11}{16}$ -in. hole in iron  $\frac{1}{4}$  in. thick, the force being applied at the end of a lever arm of  $47\frac{3}{4}$  in. The leverage would be  $47\frac{3}{4} \times 2\pi \times 21 = 6300$ . The mean force applied at the end of the lever was 95 lbs., and the force at the punch, if there was no friction, would be  $6300 \times 95 = 598,500$  lbs. The force required to punch the iron, assuming a shearing resistance of 50,000 lbs. per sq. in., would be  $50,000 \times \frac{11}{16} \times \pi \times \frac{1}{4} = 27,000$  lbs., and the efficiency of the punch would be  $27,000 \div 598,500 =$  only 4.5%. With the larger screw only used as a punch the mean force at the end of the lever was only 82 lbs. The leverage in this case was  $47\frac{3}{4} \times 2\pi \times 3 = 900$ , the total force referred to the punch, including friction,  $900 \times 82 = 73,800$ , and the efficiency  $27,000 \div 73,800 = 36.7\%$ . The screws were of tool-steel, well fitted, and lubricated with lard-oil and plumbago.

**Powell's New Screw-thread.**—A. M. Powell (*Am. Mach.*, Jan. 24, 1895) has designed a new screw-thread to replace the square form of thread, giving the advantages of greater ease in making fits, and provision for "take up" in case of wear. The dimensions are the same as those of square-thread screws, with the exception that the sides of the thread, instead of being perpendicular to the axis of the screw, are inclined  $14\frac{1}{2}^\circ$  to such perpendicular; that is, the two sides of a thread are inclined  $29^\circ$  to each other. The formulæ for dimensions of the thread are the following: Depth of thread =  $\frac{1}{2} \div$  pitch; width of top of thread = width of space at bottom =  $.3707 \div$  pitch; thickness at root of thread = width of space at top =  $.6293 \div$  pitch. The term pitch is the number of threads to the inch.

## PROPORTIONING PARTS OF MACHINES IN A SERIES OF SIZES.

(*Stevens Indicator*, April, 1892.)

The following method was used by Coleman Sellers while at William Sellers & Co.'s to get the proportions of the parts of machines, based upon the size obtained in building a large machine and a small one to any series of machines. This formula is used in getting up the proportion-book and arranging the set of proportions from which any machine can be constructed of intermediate size between the largest and smallest of the series.

**Rule to Establish Construction Formulæ.**—Take difference between the nominal sizes of the largest and the smallest machines that have been designed of the same construction. Take also the difference between the sizes of similar parts on the largest and smallest machines selected. Divide the latter by the former, and the result obtained will be a "factor," which, multiplied by the nominal capacity of the intermediate machine, and increased or diminished by a constant "increment," will give the size of the part required. To find the "increment:" Multiply the nominal capacity of some known size by the factor obtained, and subtract the result from the size of the part belonging to the machine of nominal capacity selected.

**EXAMPLE.**—Suppose the size of a part of a 72-in. machine is 3 in., and the corresponding part of a 42-in. machine is  $1\frac{7}{8}$ , or 1.875 in.: then  $72 - 42 = 30$ , and  $3 \text{ in.} - 1\frac{7}{8} \text{ in.} = 1\frac{1}{8} \text{ in.} = 1.125$ .  $1.125 \div 30 = .0375 =$  the "factor," and  $.0375 \times 42 = 1.575$ . Then  $1.875 - 1.575 = .3 =$  the "increment" to be added. Let  $D =$  nominal capacity; then the formula will read:  $x = D \times .0375 + .3$ .

*Proof:*  $42 \times .0375 + .3 = 1.875$ , or  $1\frac{7}{8}$ , the size of one of the selected parts.

Some prefer the formula:  $aD + c = x$ , in which  $D =$  nominal capacity in inches or in pounds,  $c$  is a constant increment,  $a$  is the factor, and  $x =$  the part to be found.

## KEYS.

**Sizes of Keys for Mill-gearing.** (Trans. A. S. M. E., xiii, 229.)—E. G. Parkhurst's rule: Width of key =  $\frac{1}{8}$  diam. of shaft, depth =  $\frac{1}{9}$  diam. of shaft; taper  $\frac{1}{8}$  in. to the foot.

Custom in Michigan saw-mills: Keys of square section, side =  $\frac{1}{4}$  diam. of shaft, or as nearly as may be in even sixteenths of an inch.

J. T. Hawkins's rule: Width =  $\frac{1}{8}$  diam. of hole; depth of side abutment in shaft =  $\frac{1}{8}$  diam. of hole.

W. S. Huson's rule:  $\frac{1}{2}$ -inch key for 1 to  $1\frac{1}{4}$  in. shafts,  $\frac{5}{16}$  key for  $1\frac{1}{4}$  to  $1\frac{1}{2}$  in. shafts,  $\frac{3}{8}$  in. key for  $1\frac{1}{2}$  to  $1\frac{3}{4}$  in. shafts, and so on. Taper  $\frac{1}{8}$  in. to the foot. Total thickness at large end of splice,  $\frac{4}{5}$  width of key.

Unwin (*Elements of Machine Design*) gives : Width =  $\frac{1}{4}d + \frac{1}{8}$  in. Thickness =  $\frac{1}{8}d + \frac{1}{8}$  in., in which  $d$  = diam. of shaft in inches. When wheels or pulleys transmitting only a small amount of power are keyed on large shafts, he says, these dimensions are excessive. In that case, if H.P. = horse-power transmitted by the wheel or pulley,  $N$  = revs. per min,  $P$  = force acting at the circumference, in lbs., and  $R$  = radius of pulley in inches, take

$$d = \sqrt[3]{\frac{100 \text{ H.P.}}{N}} \quad \text{or} \quad \sqrt[3]{\frac{PR}{630}}$$

Prof. Coleman Sellers (*Stevens Indicator*, April, 1892) gives the following : The size of keys, both for shafting and for machine tools, are the proportions adopted by William Sellers & Co., and rigidly adhered to during a period of nearly forty years. Their practice in making keys and fitting them is, that the keys shall always bind tight sidewise, but not top and bottom; that is, not necessarily touch either at the bottom of the key-seat in the shaft or touch the top of the slot cut in the gear-wheel that is fastened to the shaft ; but in practice keys used in this manner depend upon the fit of the wheel upon the shaft being a forcing fit, or a fit that is so tight as to require screw-pressure to put the wheel in place upon the shaft.

**Size of Keys for Shafting.**

Diameter of Shaft, in.				Size of Key, in.
1 1/4	1 7/16	1 11/16	.....	5/16 x 3/8
1 15/16	2 3/16	.....	.....	7/16 x 1/2
2 7/16	.....	.....	.....	9/16 x 5/8
2 11/16	2 15/16	3 3/16	3 7/16	.....
.....	.....	.....	.....	11/16 x 3/4
3 15/16	4 7/16	4 15/16	.....	13/16 x 7/8
5 7/16	5 15/16	6 7/16	.....	15/16 x 1
6 15/16	7 7/16	7 15/16	8 7/16	8 15/16.. 1 1/16 x 1 1/8

Length of key-seat for coupling =  $1\frac{1}{2} \times$  nominal diameter of shaft.

**Size of Keys for Machine Tools.**

Diam. of Shaft, in.	Size of Key, in. sq.	Diam. of Shaft, in.	Size of Key, in. sq.
15/16 and under	..... 1/8	4 to 5 7/16	..... 13/16

2 1/4 to 2 11/16	..... 9/16	13 to 14 15/16	..... 1 7/16
2 3/4 to 3 15/16	..... 11/16		

John Richards, in an article in *Cassier's Magazine*, writes as follows: There are two kinds or system of keys, both proper and necessary, but widely different in nature. 1. The common fastening key, usually made in width one fourth of the shaft's diameter, and the depth five eighths to one third the width. These keys are tapered and fit on all sides, or, as it is commonly described, "bear all over." They perform the double function in most cases of driving or transmitting and fastening the keyed-on member against movement endwise on the shaft. Such keys, when properly made, drive as a strut, diagonally from corner to corner.

2. The other kind or class of keys are not tapered and fit on their sides only, a slight clearance being left on the back to insure against wedge action or radial strain. These keys drive by shearing strain.

For fixed work where there is no sliding movement such keys are commonly made of square section, the sides only being planed, so the depth is more than the width by so much as is cut away in finishing or fitting.

For sliding bearings, as in the case of drilling-machine spindles, the depth should be increased, and in cases where there is heavy strain there should be two keys or feathers instead of one.

The following tables are taken from proportions adopted in practical use.

Flat keys, as in the first table, are employed for fixed work when the parts are to be held not only against torsional strain, but also against movement endwise ; and in case of heavy strain the strut principle being the strongest and most secure against movement when there is strain each way, as in the case of engine cranks and first movers generally. The objections

to the system for general use are, straining the work out of truth, the care and expense required in fitting, and destroying the evidence of good or bad fitting of the keyed joint. When a wheel or other part is fastened with a tapering key of this kind there is no means of knowing whether the work is well fitted or not. For this reason such keys are not employed by machine-tool-makers, and in the case of accurate work of any kind, indeed, cannot be, because of the wedging strain, and also the difficulty of inspecting completed work.

I. DIMENSIONS OF FLAT KEYS, IN INCHES.

Diam. of shaft.....	1	1 1/4	1 1/2	1 3/4	2	2 1/2	3	3 1/2	4	5	6	7	8

II. DIMENSIONS OF SQUARE KEYS, IN INCHES.

Diam. of shaft.....	1	1 1/4	1 1/2	1 3/4	2	2 1/2	3	3 1/2	4
Breadth of keys...	5/32	7/32	9/32	11/32	13/32	15/32	17/32	9/16	11/16
Depth of keys.....	3/16	1/4	5/16	3/8	7/16	1/2	9/16	5/8	3/4

III. DIMENSIONS OF SLIDING FEATHER-KEYS, IN INCHES.

Diam. of shaft....	1 1/4	1 1/2	1 3/4	2	2 1/4	2 1/2	3	3 1/2	4	4 1/2
Breadth of keys..	1/4	1/4	5/16	5/16	3/8	3/8	1/2	9/16	9/16	5/8
Depth of keys....	3/8	3/8	7/16	7/16	1/2	1/2	5/8	3/4	3/4	7/8

P. Prybil furnishes the following table of dimensions to the *Am. Machinist*. He says: On special heavy work and very short hubs we put in two keys in one shaft 90° apart. With special long hubs, where we cannot use keys with noses, the keys should be thicker than the standard.

Diameter of Shafts, inches.	Width, inches.	Thick-ness, in.	Diameter of Shafts, inches.	Width, inches.	Thick-ness, in.
3/4 to 1 1/16	3/16	3/16	3 7/16 to 3 11/16	7/8	5/8
1 1/8 to 1 5/16	5/16	1/4	3 15/16 to 4 3/16	1	11/16
1 7/16 to 1 11/16	3/8	5/16	4 7/16 to 4 11/16	1 1/8	3/4
1 15/16 to 2 3/16	1/2	3/8	4 7/8 to 5 3/8	1 1/4	15/16
2 7/16 to 2 11/16	5/8	1/2	5 7/8 to 6 3/8	1 1/2	1
2 15/16 to 3 3/16	3/4	9/16	6 7/8 to 7 3/8	1 3/4	1 1/8

Keys longer than 10 inches, say 14 to 16", 1/16" thicker; keys longer than 10 inches, say 18 to 20", 1/8" thicker; and so on. Special short hubs to have two keys.

For description of the Woodruff system of keying, see circular of the Pratt & Whitney Co.; also *Modern Mechanism*, page 455.

HOLDING-POWER OF KEYS AND SET-SCREWS.

**Tests of the Holding-power of Set-screws in Pulleys.** (G. Lanza, *Trans. A. S. M. E.*, x. 230.)—These tests were made by using a pulley fastened to the shaft by two set-screws with the shaft keyed to the holders; then the load required at the rim of the pulley to cause it to slip was determined, and this being multiplied by the number 6.037 (obtained by adding to the radius of the pulley one-half the diameter of the wire rope, and dividing the sum by twice the radius of the shaft, since there were two set-screws in action at a time) gives the holding-power of the set-screws. The set-screws used were of wrought-iron, 5/8 of an inch in diameter, and ten threads to the inch; the shaft used was of steel and rather hard, the set-screws making but little impression upon it. They were set up with a force of 75 lbs. at the end of a ten-inch monkey-wrench. The set-screws used were of four kinds, marked respectively A, B, C, and D. The results were as follows:

A, ends perfectly flat, 9/16-in. diameter,	1412 to 2294 lbs.;	average 2064.
B, radius of rounded ends about $\frac{1}{2}$ inch,	2747 " 3079 "	" 2912.
C, " " " " " $\frac{1}{4}$ "	1902 " 3079 "	" 2573.
D ends cup-shaped and case-hardened,	1962 " 2958 "	" 2470.

REMARKS.—A. The set-screws were not entirely normal to the shaft; hence they bore less in the earlier trials, before they had become flattened by wear.

B. The ends of these set-screws, after the first two trials, were found to be flattened, the flattened area having a diameter of about  $\frac{1}{4}$  inch.

C. The ends were found, after the first two trials, to be flattened, as in B.

D. The first test held well because the edges were sharp, then the holding-power fell off till they had become flattened in a manner similar to B, when the holding-power increased again.

**Tests of the Holding-power of Keys.** (Lanza.)—The load was applied as in the tests of set-screws, the shaft being firmly keyed to the holders. The load required at the rim of the pulley to shear the keys was determined, and this, multiplied by a suitable constant, determined in a similar way to that used in the case of set-screws, gives us the shearing strength per square inch of the keys.

The keys tested were of eight kinds, denoted, respectively, by the letters A, B, C, D, E, F, G and H, and the results were as follows: A, B, D and F, each 4 tests; E, 3 tests; C, G, and H, each 2 tests.

A, Norway iron, $2'' \times \frac{1}{4}'' \times 15/32''$ ,	40,184 to 47,760 lbs.;	average, 42,726.
B, refined iron, $2'' \times \frac{1}{4}'' \times 15/32''$ ,	36,482 " 39,254;	" 38,059.
C, tool steel, $1'' \times \frac{1}{4}'' \times 15/32''$ ,	91,344 & 100,056.	
D, machinery steel, $2'' \times \frac{1}{4}'' \times 15/32''$ ,	64,630 to 70,186;	" 66,875.
E, Norway iron, $1\frac{1}{8}'' \times \frac{3}{8}'' \times 7/16''$ ,	36,850 " 37,222;	" 37,036.
F, cast-iron, $2'' \times \frac{1}{4}'' \times 15/32''$ ,	30,278 " 36,944;	" 33,034.
G, cast-iron, $1\frac{1}{8}'' \times \frac{3}{8}'' \times 7/16''$ ,	37,222 & 38,700.	
H, cast-iron, $1'' \times \frac{1}{2}'' \times 7/16''$ ,	29,814 & 38,978.	

In A and B some crushing took place before shearing. In E, the keys being only  $7/16$  in. deep, tipped slightly in the key-way. In H, in the first test, there was a defect in the key-way of the pulley.

## DYNAMOMETERS.

Dynamometers are instruments used for measuring power. They are of several classes, as: 1. Traction dynamometers, used for determining the power required to pull a car or other vehicle, or a plough or harrow. 2. Brake or absorption dynamometers, in which the power of a rotating shaft or wheel is absorbed or converted into heat by the friction of a brake; and, 3. Transmission dynamometers, in which the power in a rotating shaft is measured during its transmission through a belt or other connection to another shaft, without being absorbed.

**Traction Dynamometers** generally contain two principal parts: (1) A spring or series of springs, through which the pull is exerted, the extension of the spring measuring the amount of the pulling force; and (2) a paper-covered drum, rotated either at a uniform speed by clockwork, or at a speed proportional to the speed of the traction, through gearing, on which the extension of the spring is registered by a pencil. From the average height of the diagram drawn by the pencil above the zero-line the average pulling force in pounds is obtained, and this multiplied by the distance traversed, in feet, gives the work done, in foot-pounds. The product divided by the time in minutes and by 33,000 gives the horse-power.

**The Prony brake** is the typical form of absorption dynamometer. (See Fig. 167, from Flather on Dynamometers and the Measurement of Power.)

Primarily this consists of a lever connected to a revolving shaft or pulley in such a manner that the friction induced between the surfaces in contact will tend to rotate the arm in the direction in which the shaft revolves. This rotation is counterbalanced by weights *P*, hung in the scale-pan at the end of the lever. In order to measure the power for a given number of revolutions of pulley, we add weights to the scale-pan and screw up on bolts *bb*, until the friction induced balances the weights and the lever is maintained

in its horizontal position while the revolutions of shaft per minute remain constant.

For small powers the beam is generally omitted—the friction being measured by weighting a band or strap thrown over the pulley. Ropes or cords are often used for the same purpose.

Instead of hanging weights in a scale-pan, as in Fig. 167, the friction may be weighed on a platform-scale; in this case, the direction of rotation being the same, the lever-arm will be on the opposite side of the shaft.

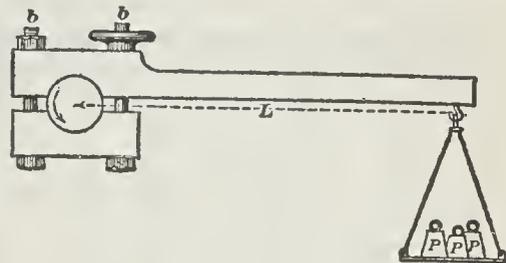

FIG. 167.

In a modification of this brake, the brake-wheel is keyed to the shaft, and its rim is provided with inner flanges which form an annular trough for the retention of water to keep the pulley from heating. A small stream of water constantly discharges into the trough and revolves with the pulley—the centrifugal force of the particles or water overcoming the action of gravity; a waste-pipe with its end flattened is so placed in the trough that it acts as a scoop, and removes all surplus water. The brake consists of a flexible strap to which are fitted blocks of wood forming the rubbing-surface; the ends of the strap are connected by an adjustable bolt-clamp, by means of which any desired tension may be obtained.

The horse-power or work of the shaft is determined from the following:

- Let  $W$  = work of shaft, equals power absorbed, per minute;
- $P$  = unbalanced pressure or weight in pounds, acting on lever-arm at distance  $L$ ;
- $L$  = length of lever-arm in feet from centre of shaft;
- $V$  = velocity of a point in feet per minute at distance  $L$ , if arm were allowed to rotate at the speed of the shaft;
- $N$  = number of revolutions per minute;
- H.P. = horse-power.

Then will  $W = PV = 2\pi LNP$ .

Since H.P. =  $PV \div 33,000$ , we have H.P. =  $2\pi LNP \div 33,000$ .

If  $L = \frac{33}{2\pi}$ , we obtain H.P. =  $\frac{NP}{1000}$ .  $33 \div 2\pi$  is practically 5 ft. 3 in., a value

often used in practice for the length of arm.

If the rubbing-surface be too small, the resulting friction will show great irregularity—probably on account of insufficient lubrication—the jaws being allowed to seize the pulley, thus producing shocks and sudden vibrations of the lever-arm.

Soft woods, such as bass, plane-tree, beech, poplar, or maple are all to be preferred to the harder woods for brake-blocks. The rubbing-surface should be well lubricated with a heavy grease.

**The Alden Absorption-dynamometer.** (G. I. Alden, Trans. A. S. M. E., vol. xi. 958; also xii. 700 and xiii. 429.)—This dynamometer is a friction-brake, which is capable in quite moderate sizes of absorbing large powers with unusual steadiness and complete regulation. A smooth cast-iron disk is keyed on the rotating shaft. This is enclosed in a cast-iron shell, formed of two disks and a ring at their circumference, which is free to revolve on the shaft. To the interior of each of the sides of the shell is fitted a copper plate, enclosing between itself and the side a water-tight space. Water under pressure from the city pipes is admitted into each of these spaces, forcing the copper plate against the central disk. The chamber enclosing the disk is filled with oil. To the outer shell is fixed a weighted arm, which resists the tendency of the shell to rotate with the shaft, caused by the friction of the plates against the central disk. Four brakes of this type, 56 in. diam., were used in testing the experimental locomotive at Purdue University (Trans. A. S. M. E., xiii. 429). Each was designed for a maximum moment of 10,500 foot-pounds with a water-pressure of 40 lbs. per sq. in.

The area in effective contact with the copper plates on either side is represented by an annular surface having its outer radius equal to 28 inches, and its inner radius equal to 10 inches. The apparent coefficient of friction between the plates and the disk was  $3\frac{1}{2}\%$ .

W. W. Beaumont (Proc. Inst. C. E. 1889) has deduced a formula by means of which the relative capacity of brakes can be compared, judging from the amount of horse-power ascertained by their use.

If  $W$  = width of rubbing-surface on brake-wheel in inches;  $V$  = vel. of point on circum. of wheel in feet per minute;  $K$  = coefficient; then

$$K = WV + \text{H.P.}$$

**Capacity of Friction-brakes.**—Prof. Flather obtains the values of  $K$  given in the last column of the subjoined table :

Horse-power.	R. P. M. Brake-pulley.	Brake-pulley.		Length of Arm.	Design of Brake.	Value of $K$ .
		Face, in inches.	Diameter, in feet.			
21	150	7	5	33"	Royal Ag. Soc., compensating.....	785
19	148.5	7	5	33.38"	McLaren, compensating .....	858
20	146	7	5	32.19"	" water-cooled and comp.....	802
40	180	10.5	5	32"	Garrett, " " " " .....	741
33	150	10.5	5	32"	" " " " .....	749
150	150	10	9	.....	Schoenheyder, water-cooled.....	282
24	142	12	6	38.31"	Balk.....	1385
180	100	24	5	126.1"	Gately & Kletsch, water-cooled.....	209
475	76.2	24	7	191"	Webber, water-cooled .....	84.7
125	290	24	4	63"	Westinghouse, water-cooled.....	465
250	250					
40	322	13	4	27 $\frac{3}{4}$ "	" " .....	847
125	290					

The above calculations for eleven brakes give values of  $K$  varying from 84.7 to 1385 for actual horse-powers tested, the average being  $K = 655$ .

Instead of assuming an average coefficient, Prof. Flather proposes the following :

Water-cooled brake, non-compensating,  $K = 400$ ;  $W = 400 \text{ H.P.} + V$ .

Water-cooled brake, compensating.  $K = 750$ ;  $W = 750 \text{ H.P.} + V$ .

Non-cooling brake, with or without compensating device,  $K = 900$ ;  $W = 900 \text{ H.P.} + V$ .

**Transmission Dynamometers** are of various forms, as the Batchelder dynamometer, in which the power is transmitted through a "train-arm" of bevel gearing, with its modifications, as the one described by the author in Trans. A. I. M. E., viii. 177, and the one described by Samuel Webber in Trans. A. S. M. E., x. 514; belt dynamometers, as the Tatham; the Van Winkle dynamometer, in which the power is transmitted from a revolving shaft to another in line with it, the two almost touching, through the medium of coiled springs fastened to arms or disks keyed to the shafts; the Brackett and the Webb cradle dynamometers, used for measuring the power required to run dynamo-electric machines. Descriptions of the four last named are given in Flather on Dynamometers.

Much information on various forms of dynamometers will be found in Trans. A. S. M. E., vol. vii. to xv., inclusive, indexed under Dynamometers

## ICE-MAKING OR REFRIGERATING MACHINES.

**References.**—An elaborate discussion of the thermodynamic theory of the action of the various fluids used in the production of cold was published by M. Ledoux in the *Annales des Mines*, and translated in *Van Nostrand's Magazine* in 1879. This work, revised and additions made in the light of recent experience by Professors Denton, Jacobus, and Riesenberger, was reprinted in 1892. (Van Nostrand's Science Series, No. 46.) The work is largely mathematical, but it also contains much information of immediate practical value, from which some of the matter given below is taken. Other references are Wood's Thermodynamics, Chap. V., and numerous papers by Professors Wood, Denton, Jacobus, and Linde in *Trans. A. S. M. E.*, vols. x. to xiv.; Johnson's Cyclopædia, article on Refrigerating-machines; also *Eng'g*, June 18, July 2 and 9, 1886; April 1, 1887; June 15, 1888; July 31, Aug. 28, 1889; Sept. 11 and Dec. 4, 1891; May 6 and July 8, 1892. For properties of Ammonia and Sulphur Dioxide, see papers by Professors Wood and Jacobus, *Trans. A. S. M. E.*, vols. x. and xii.

For illustrated articles describing refrigerating-machines, see *Am. Mach.*, May 29 and June 26, 1890, and *Mfrs. Record*, Oct. 7, 1892; also catalogues of builders, as Frick & Co., Waynesboro, Pa.; De La Vergne Refrigerating-machine Co., New York; and others.

**Operations of a Refrigerating-machine.**—Apparatus designed for refrigerating is based upon the following series of operations:

Compress a gas or vapor by means of some external force, then relieve it of its heat so as to diminish its volume; next, cause this compressed gas or vapor to expand so as to produce mechanical work, and thus lower its temperature. The absorption of heat at this stage by the gas, in resuming its original condition, constitutes the refrigerating effect of the apparatus.

A refrigerating-machine is a heat-engine reversed.

From this similarity between heat-motors and freezing-machines it results that all the equations deduced from the mechanical theory of heat to determine the performance of the first, apply equally to the second.

The efficiency depends upon the difference between the extremes of temperature.

The useful effect of a refrigerating-machine depends upon the ratio between the heat-units eliminated and the work expended in compressing and expanding.

This result is independent of the nature of the body employed.

Unlike the heat-motors, the freezing-machine possesses the greatest efficiency when the range of temperature is small, and when the final temperature is elevated.

If the temperatures are the same, there is no theoretical advantage in employing a gas rather than a vapor in order to produce cold.

The choice of the intermediate body would be determined by practical considerations based on the physical characteristics of the body, such as the greater or less facility for manipulating it, the extreme pressures required for the best effects, etc.

Air offers the double advantage that it is everywhere obtainable, and that we can vary at will the higher pressures, independent of the temperature of the refrigerant. But to produce a given useful effect the apparatus must be of larger dimensions than that required by liquefiable vapors.

The maximum pressure is determined by the temperature of the condenser and the nature of the volatile liquid; this pressure is often very high.

When a change of volume of a saturated vapor is made under constant pressure, the temperature remains constant. The addition or subtraction of heat, which produces the change of volume, is represented by an increase or a diminution of the quantity of liquid mixed with the vapor.

On the other hand, when vapors, even if saturated, are no longer in contact with their liquids, and receive an addition of heat either through compression by a mechanical force, or from some external source of heat, they comport themselves nearly in the same way as permanent gases, and become superheated.

It results from this property, that refrigerating-machines using a liquefiable gas will afford results differing according to the method of working,

and depending upon the state of the gas, whether it remains constantly saturated, or is superheated during a part of the cycle of working.

The temperature of the condenser is determined by local conditions. The interior will exceed by 9° to 18° the temperature of the water furnished to the exterior. This latter will vary from about 52° F., the temperature of water from considerable depth below the surface, to about 95° F., the temperature of surface-water in hot climates. The volatile liquid employed in the machine ought not at this temperature to have a tension above that which can be readily managed by the apparatus.

On the other hand, if the tension of the gas at the minimum temperature is too low, it becomes necessary to give to the compression-cylinder large dimensions, in order that the weight of vapor compressed by a single stroke of the piston shall be sufficient to produce a notably useful effect.

These two conditions, to which may be added others, such as those depending upon the greater or less facility of obtaining the liquid, upon the dangers incurred in its use, either from its inflammability or unhealthfulness, and finally upon its action upon the metals, limit the choice to a small number of substances.

The gases or vapors generally available are: sulphuric ether, sulphurous oxide, ammonia, methylic ether, and carbonic acid.

The following table, derived from Regnault, shows the tensions of the vapors of these substances at different temperatures between - 22° and + 104°.

### Pressures and Boiling-points of Liquids available for Use in Refrigerating-machines.

Temp. of Ebullition.	Tension of Vapor, in lbs. per sq. in., above Zero.

104	17.59	90.32	227.76	.....	1338.2	82.9

The table shows that the use of ether does not readily lead to the production of low temperatures, because its pressure becomes then very feeble.

Ammonia, on the contrary, is well adapted to the production of low temperatures.

Methylic ether yields low temperatures without attaining too great pressures at the temperature of the condenser. Sulphur dioxide readily affords temperatures of - 14 to - 5, while its pressure is only 3 to 4 atmospheres at the ordinary temperature of the condenser. These latter substances then lend themselves conveniently for the production of cold by means of mechanical force.

The "Pictet fluid" is a mixture of 97% sulphur dioxide and 3% carbonic acid. At atmospheric pressure it affords a temperature 14° lower than sulphur dioxide.

Carbonic acid is as yet (1895) in use but to a limited extent, but the relatively greater compactness of compressor that it requires, and its inoffensive

character, are leading to its recommendation for service on shipboard, where economy of space is important.

Certain ammonia plants are operated with a surplus of liquid present during compression, so that superheating is prevented. This practice is known as the "cold system" of compression.

Nothing definite is known regarding the application of methylic ether or of the petroleum product chymogene in practical refrigerating service. The inflammability of the latter and the cumbrousness of the compressor required are objections to its use.

**"Ice-melting Effect."**—It is agreed that the term "ice-melting effect" means the cold produced in an insulated bath of brine, on the assumption that each 142.2 B.T.U.\* represents one pound of ice, this being the latent heat of fusion of ice, or the heat required to melt a pound of ice at 32° to water at the same temperature.

The performance of a machine, expressed in pounds or tons of "ice-melting capacity," does not mean that the refrigerating-machine would make the same amount of actual ice, but that the cold produced is equivalent to the effect of the melting of ice at 32° to water of the same temperature.

In making artificial ice the water frozen is generally about 70° F. when submitted to the refrigerating effect of a machine; second, the ice is chilled from 12° to 20° below its freezing-point; third, there is a dissipation of cold, from the exposure of the brine tank and the manipulation of the ice-cans: therefore the weight of actual ice made, multiplied by its latent heat of fusion, 142.2 thermal units, represents only about three fourths of the cold produced in the brine by the refrigerating fluid per I.H.P. of the engine driving the compressing-pumps. Again, there is considerable fuel consumed to operate the brine-circulating pump, the condensing-water and feed-pumps, and to reboil, or purify, the condensed steam from which the ice is frozen. This fuel, together with that wasted in leakage and drip water, amounts to about one half that required to drive the main steam-engine. Hence the pounds of actual ice manufactured from distilled water is just about half the equivalent of the refrigerating effect produced in the brine per indicated horsepower of the steam-cylinders.

When ice is made directly from natural water by means of the "plate system," about half of the fuel, used with distilled water, is saved by avoiding the reboiling, and using steam expansively in a compound engine.

**Ether-machines**, used in India, are said to have produced about 6 lbs. of actual ice per pound of fuel consumed.

The ether machine is obsolete, because the density of the vapor of ether, at the necessary working-pressure, requires that the compressing-cylinder shall be about 6 times larger than for sulphur dioxide, and 17 times larger than for ammonia.

**Air-machines** require about 1.2 times greater capacity of compressing cylinder, and are, as a whole, more cumbersome than ether machines, but they remain in use on ship-board. In using air the expansion must take place in a cylinder doing work, instead of through a simple expansion-cock which is used with vapor machines. The work done in the expansion-cylinder is utilized in assisting the compressor.

**Ammonia Compression-machines.**—"Cold" vs. "Dry" Systems of Compression.—In the "cold" system or "humid" system some of the ammonia entering the compression-cylinder is liquid, so that the heat developed in the cylinder is absorbed by the liquid and the temperature of the ammonia thereby confined to the boiling-point due to the condenser-pressure. No jacket is therefore required about the cylinder.

In the "dry" or "hot" system all ammonia entering the compressor is gaseous, and the temperature becomes by compression several hundred degrees greater than the boiling-point due to the condenser-pressure. A water-jacket is therefore necessary to permit the cylinder to be properly lubricated.

**Relative Performance of Ammonia Compression- and Absorption-machines, assuming no Water to be Entrained with the Ammonia-gas in the Condenser.** (Denton and Jacobus, Trans. A. S. M. E., xiii.)—It is assumed in the calculation for both machines that 1 lb. of coal imparts 10,000 B.T.U. to the boiler. The

\* The latent heat of fusion of ice is 144 thermal units (*Phil. Mag.*, 1871, xli., 182); but it is customary to use 142. (Prof. Wood, Trans. A. S. M. E., xi. 834.)

condensed steam from the generator of the absorption-machine is assumed to be returned to the boiler at the temperature of the steam entering the generator. The engine of the compression-machine is assumed to exhaust through a feed-water heater that heats the feed-water to 213° F. The engine is assumed to consume 26¼ lbs. of water per hour per horse-power. The figures for the compression-machine include the effect of friction, which is taken at 15% of the net work of compression.

Condenser.		Refrigerating Coils.		Temp. of Absorber, degrees F.	Pounds of Ice-melting Effect per lb. of Coal.				Heat furnished to generator of absorption-machine, B.T.U. per lb. of ammonia circulated.

**The Ammonia Absorption-machine** comprises a generator which contains a concentrated solution of ammonia in water; this generator is heated either directly by a fire, or indirectly by pipes leading from a steam-boiler. The condenser communicates with the upper part of the generator by a tube; it is cooled externally by a current of cold water. The cooler or brine-tank is so constructed as to utilize the cold produced; the upper part of it is in communication with the lower part of the condenser.

An absorption-chamber is filled with a weak solution of ammonia; a tube puts this chamber in communication with the cooling-tank.

The absorption-chamber communicates with the boiler by two tubes: one leads from the bottom of the generator to the top of the chamber, the other leads from the bottom of the chamber to the top of the generator. Upon the latter is mounted a pump, to force the liquid from the absorption-chamber, where the pressure is maintained at about one atmosphere, into the generator, where the pressure is from 8 to 12 atmospheres.

To work the apparatus the ammonia solution in the generator is first heated. This releases the gas from the solution, and the pressure rises. When it reaches the tension of the saturated gas at the temperature of the condenser there is a liquefaction of the gas, and also of a small amount of steam. By means of a cock the flow of the liquefied gas into the refrigerating-coils contained in the cooler is regulated. It is here vaporized by absorbing the heat from the substance placed there to be cooled. As fast as it is vaporized it is absorbed by the weak solution in the absorbing-chamber.

Under the influence of the heat in the boiler the solution is unequally saturated, the stronger solution being uppermost.

The weaker portion is conveyed by the pipe entering the top of the absorbing-chamber, the flow being regulated by a cock, while the pump sends an equal quantity of strong solution from the chamber back to the boiler.

\* 5% of water entrained in the ammonia will lower the economy of the absorption-machine about 15% to 20% below the figures given in the table.

The working of the apparatus depends upon the adjustment and regulation of the flow of the gas and liquid; by these means the pressure is varied, and consequently the temperature in the cooler may be controlled.

The working is similar to that of compression-machines. The absorption-chamber fills the office of aspirator, and the generator plays the part of compressor.

The mechanical force producing exhaustion is here replaced by the affinity of water for ammonia gas; and the mechanical force required for compression is replaced by the heat which severs this affinity and sets the gas at liberty.

(For discussion of the efficiency of the absorption system, see Ledoux's work; paper by Prof. Linde, and discussion on the same by Prof. Jacobus, Trans. A. S. M. E., xiv. 1416, 1436; and papers by Denton and Jacobus, Trans. A. S. M. E. x. 792; xiii. 507.

**Sulphur-Dioxide Machines.**—Results of theoretical calculations are given in a table by Ledoux showing an ice-melting capacity per hour per horse-power ranging from 134 to 63 lbs., and per pound of coal ranging from 44.7 to 21.1 lbs., as the temperature corresponding to the pressure of the vapor in the condenser rises from 59° to 104° F. The theoretical results do not represent the actual. It is necessary to take into account the loss occasioned by the pipes, the waste spaces in the cylinder, loss of time in opening of the valves, the leakage around the piston and valves, the reheating by the external air, and finally, when the ice is being made, the quantity of the ice melted in removing the blocks from their moulds. Manufacturers estimate that practically the sulphur-dioxide apparatus using water at 55° or 60° F. produces 56 lbs. of ice, or about 10,000 heat-units, per hour per horse-power, measured on the driving-shaft, which is about 55% of the theoretical useful effect. In the commercial manufacture of ice about 7 lbs. are produced per pound of coal. This includes the fuel used for re-boiling the water, which, together with that wasted by the pumps and lost by radiation, amounts to a considerable portion of that used by the engine.

Prof. Denton says concerning Ledoux's theoretical results: The figures given are higher than those obtained in practice, because the effect of superheating of the gas during admission to the cylinder is not considered. This superheating may cause an increase of work of about 25%. There are other losses due to superheating the gas at the brine-tank, and in the pipe leading from the brine-tank to the compressor, so that in actual practice a sulphur-dioxide machine, working under the conditions of an absolute pressure in the condenser of 56 lbs. per sq. in. and the corresponding temperature of 77° F., will give about 22 lbs. of ice-melting capacity per pound of coal, which is about 60% of the theoretical amount neglecting friction, or 70% including friction. The following tests, selected from those made by Prof. Schröter on a Pictet ice-machine having a compression-cylinder 11.3 in. bore and 24.4 in. stroke, show the relation between the theoretical and actual ice-melting capacity.

No. of Test.	Temp. in degrees Fahr. corresponding to pressure of vapor.		Ice-melting capacity per pound of coal, assuming 3 lbs. per hour per H.P.

12	76.2	14.4	31.2	24.1	22.8
13	75.2	-2.5	23.0	17.5	23.9
14	80.6	-15.9	16.6	10.1	39.2

**The Refrigerating Coils** of a Pictet ice-machine described by Ledoux had 79 sq. ft. of surface for each 100,000 theoretic negative heat-units produced per hour. The temperature corresponding to the pressure of the dioxide in the coils is 10.4° F., and that of the bath (calcium chloride solution) in which they were immersed is 19.4°.

\* Friction taken at figure observed in the test, which ranged from 23% to 26% of the work of the steam-cylinder.

**Ammonia Compression-machines.**—Ammonia gas possesses the advantage or affording about three times the useful effect of sulphur dioxide for the same volume described by the piston.  
 The perfection of ammonia apparatus now renders it so convenient and reliable that no practical advantage, results from the lower pressures afforded by sulphur dioxide.  
 The results of the calculations for ammonia are given in the table below :

PERFORMANCE OF AMMONIA COMPRESSION-MACHINES.

The theoretical results for ammonia are higher than the actual, for the same reasons that have been stated for sulphur dioxide. In the case of ammonia the action of the cylinder-walls in superheating the entering vapor has been determined experimentally by Prof. Denton, and the amount found to agree with that indicated by theory. In these experiments the ammonia circulated in a 75-ton refrigerating machine was measured directly by means of a special meter, so that in addition to determining the effect of superheating, the latent heats can be calculated at the suction and condenser pressure.

### Refrigerating Machines using Vapor of Water. (Ledoux.)

—In these machines, sometimes called vacuum machines, water, at ordinary temperatures, is injected into, or placed in connection with, a chamber in which a strong vacuum is maintained. A portion of the water vaporizes, the heat to cause the vaporization being supplied from the water not vaporized, so that the latter is chilled or frozen to ice. If brine is used instead of pure water, its temperature may be reduced below the freezing-point of water. The water vapor is compressed from, say, a pressure of one tenth of a pound per square inch to one and one half pounds, and discharged into a condenser. It is then condensed and removed by means of an ordinary air-pump. The principle of action of such a machine is the same as that of volatile-vapor machines.

A theoretical calculation for ice-making, assuming a lower temperature of 32° F., a pressure in the condenser of  $1\frac{1}{2}$  lbs. per square inch, and a coal consumption of 3 lbs. per I.H.P. per hour, gives an ice-melting effect of 34.5 lbs. per pound of coal, neglecting friction. Ammonia for ice-making conditions gives 40.9 lbs. The volume of the compressing cylinder is about 150 times the theoretical volume for an ammonia machine for these conditions.

**Relative Efficiency of a Refrigerating Machine.**—The efficiency of a refrigerating machine is sometimes expressed as the quotient of the quantity of heat received by the ammonia from the brine, that is, the quantity of useful work done, divided by the heat equivalent of the mechanical work done in the compressor. Thus in column 1 of the table of performance of the 75-ton machine (page 998) the heat given by the brine to the ammonia per minute is 14,776 B.T.U. The horse-power of the ammonia cylinder is 65.7, and its heat equivalent =  $65.7 \times 33,000 \div 778 = 2786$  B.T.U. Then  $14,776 \div 2786 = 5.304$ , efficiency. The apparent paradox that the efficiency is greater than unity, which is impossible in any machine, is thus explained. The working fluid, as ammonia, receives heat from the brine and rejects heat into the condenser. (If the compressor is jacketed, a portion is rejected into the jacket-water.) The heat rejected into the condenser is greater than that received from the brine; the difference (plus or minus a small difference radiated to or from the atmosphere) is heat received by the ammonia from the compressor. The work to be done by the compressor is not the mechanical equivalent of the refrigeration of the brine, but only that necessary to supply the difference between the heat rejected by the ammonia into the condenser and that received from the brine. If cooling water colder than the brine were available, the brine might transfer its heat directly into the cooling water, and there would be no need of ammonia or of a compressor; but

\* Friction taken at figures observed in the tests, which range from 14% to 20% of the work of the steam-cylinder.

since such cold water is not available, the brine rejects its heat into the colder ammonia, and then the compressor is required to heat the ammonia to such a temperature that it may reject heat into the cooling water.

The efficiency of a refrigerating plant referred to the amount of fuel consumed is

$$\text{Ice-melting capacity per pound of fuel.} \left. \vphantom{\text{Ice-melting capacity}} \right\} = \frac{\left\{ \begin{array}{l} \text{Pounds circulated per hour} \\ \times \text{specific heat} \times \text{range} \\ \text{of temperature} \end{array} \right\} \text{ of brine or other circulating fluid.}}{142.2 \times \text{pounds of fuel used per hour.}}$$

The ice-melting capacity is expressed as follows:

$$\text{Tons (of 2000 lbs.) ice-melting capacity per 24 hours} \left. \vphantom{\text{Tons}} \right\} = \frac{\left\{ \begin{array}{l} 24 \times \text{pounds} \\ \times \text{specific heat} \\ \times \text{range of temp.} \end{array} \right\} \text{ of brine circulated per hour.}}{142.2 \times 2000}$$

The analogy between a heat-engine and a refrigerating-machine is as follows: A steam-engine receives heat from the boiler, converts a part of it into mechanical work in the cylinder, and throws away the difference into the condenser. The ammonia in a compression refrigerating-machine receives heat from the brine-tank or cold-room, receives an additional amount of heat from the mechanical work done in the compression-cylinder, and throws away the sum into the condenser. The efficiency of the steam-engine = work done ÷ heat received from boiler. The efficiency of the refrigerating-machine = heat received from the brine-tank or cold-room ÷ heat required to produce the work in the compression-cylinder. In the ammonia

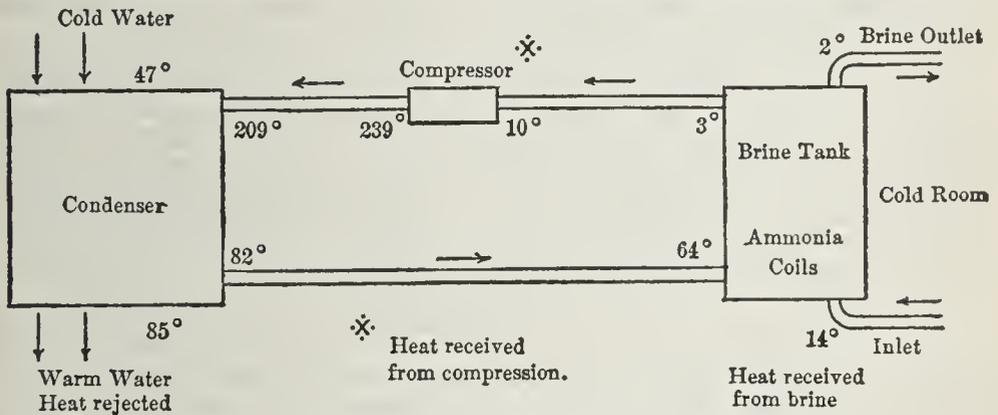

DIAGRAM OF AMMONIA COMPRESSION MACHINE.

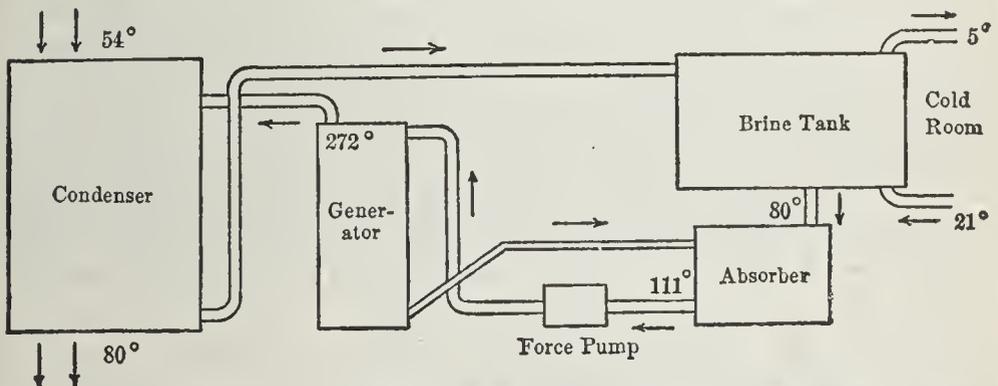

DIAGRAM OF AMMONIA ABSORPTION MACHINE.

absorption-apparatus, the ammonia receives heat from the brine-tank and additional heat from the boiler or generator, and rejects the sum into the condenser and into the cooling water supplied to the absorber. The efficiency = heat received from the brine ÷ heat received from the boiler.

**TEST-TRIALS OF REFRIGERATING-MACHINES.**

(G. Linde, Trans. A. S. M. E., xiv. 1414.)

The purpose of the test is to determine the ratio of consumption and production, so that there will have to be measured both the refrigerative effect and the heat (or mechanical work) consumed, also the cooling water. The refrigerative effect is the product of the number of heat-units ( $Q$ ) abstracted from the body to be cooled, and the quotient  $\frac{T_c - T}{T}$ ; in which  $T_c =$  abso-

lute temperature at which heat is transmitted to the cooling water, and  $T =$  absolute temperature at which heat is taken from the body to be cooled.

The determination of the quantity of cold will be possible with the proper exactness only when the machine is employed during the test to refrigerate a liquid; and if the cold be found from the quantity of liquid circulated per unit of time, from its range of refrigeration, and from its specific heat. Sufficient exactness cannot be obtained by the refrigeration of a current of circulating air, nor from the manufacture of a certain quantity of ice, nor from a calculation of the fluid circulating within the machine (for instance, the quantity of ammonia circulated by the compressor). Thus the refrigeration of brine will generally form the basis for tests making any pretension to accuracy. The degree of refrigeration should not be greater than necessary for allowing the range of temperature to be measured with the necessary exactness; a range of temperature of from 5° to 6° Fahr. will suffice.

The condenser measurements for cooling water and its temperatures will be possible with sufficient accuracy only with submerged condensers.

The measurement of the quantity of brine circulated, and of the cooling water, is usually effected by water-meters inserted into the conduits. If the necessary precautions are observed, this method is admissible. For quite precise tests, however, the use of two accurately gauged tanks must be advised, which are alternately filled and emptied.

To measure the temperatures of brine and cooling water at the entrance and exit of refrigerator and condenser respectively, the employment of specially constructed and frequently standardized thermometers is indispensable; no less important is the precaution of using at each spot simultaneously two thermometers, and of changing the position of one such thermometer series from inlet to outlet (and *vice versa*) after the expiration of one half of the test, in order that possible errors may be compensated.

It is important to determine the specific heat of the brine used in each instance for its corresponding temperature range, as small differences in the composition and the concentration may cause considerable variations.

As regards the measurement of consumption, the programme will not have any special rules in cases where only the measurement of steam and cooling water is undertaken, as will be mainly the case for trials of absorption-machines. For compression-machines the steam consumption depends both on the quality of the steam-engine and on that of the refrigerating-machine, while it is evidently desirable to know the consumption of the former separately from that of the latter. As a rule steam-engine and compressor are coupled directly together, thus rendering a direct measurement of the power absorbed by the refrigerating-machine impossible, and it will have to suffice to ascertain the indicated work both of steam-engine and compressor. By further measuring the work for the engine running empty, and by comparing the differences in power between steam-engine and compressor resulting for wide variations of condenser-pressures, the effective consumption of work  $L_e$  for the refrigerating-machine can be found very closely. In general, it will suffice to use the indicated work found in the steam-cylinder, especially as from this observation the expenditure of heat can be directly determined. Ordinarily the use of the indicated work in the compressor-cylinder, for purposes of comparison, should be avoided; firstly, because there are usually certain accessory apparatus to be driven (agitators, etc.), belonging to the refrigerating-machine proper; and secondly, because the external friction would be excluded.

**Heat Balance.**—We possess an important aid for checking the correctness of the results found in each trial by forming the balance in each case for the heat received and rejected. Only such tests should be regarded as correct beyond doubt which show a sufficient conformity in the heat balance. It is true that in certain instances it may not be easy to account fully for the transmission of heat between the several parts of the machine and its environment by radiation and convection, but generally

$$\frac{AL}{Q'} = u, \text{ and } \frac{Q'}{Q} = \frac{T_c - T}{uT}.$$

It follows that the expenditure of heat  $Q'$  necessary for the production of the quantity of cold  $Q$  in a compression-machine will be the smaller, the smaller the difference of temperature  $T_c - T$ .

**Metering the Ammonia.**—For a complete test of an ammonia refrigerating-machine it is advisable to measure the quantity of ammonia circulated, as was done in the test of the 75-ton machine described by Prof. Denton. (Trans. A. S. M. E., xii. 326.)

**Density of Liquid Ammonia.** (D'Andreff, Trans. A. S. M. E., x. 641.)

At temperature C.....	-10	-5	0	5	10	15	20
" " F.....	+14	23	32	41	50	59	68
Density.....	.6492	.6429	.6364	.6298	.6230	.6160	.6089

These may be expressed very nearly by

$$\delta = 0.6364 - 0.0014t^\circ \text{ Centigrade};$$

$$\delta = 0.6502 - 0.000777T^\circ \text{ Fahr.}$$

**Latent Heat of Evaporation of Ammonia.** (Wood, Trans. A. S. M. E., x. 641.)

$$he = 555.5 - 0.613T - 0.000219T^2 \text{ (in B.T.U., Fahr. deg.);}$$

$$\text{Ledoux found } he = 583.33 - 0.5499T - 0.0001173T^2.$$

For experimental values at different temperatures determined by Prof. Denton, see Trans. A. S. M. E., xii. 356. For calculated values, see vol. x. 646.

**Density of Ammonia Gas.**—Theoretical, 0.5894; experimental, 0.596. Regnault (Trans. A. S. M. E., x. 633).

**Specific Heat of Liquid Ammonia.** (Wood, Trans. A. S. M. E., x. 645)—The specific heat is nearly constant at different temperatures, and about equal to that of water, or unity. From 0° to 100° F., it is

$$c = 1.096 - .0012T, \text{ nearly.}$$

In a later paper by Prof. Wood (Trans. A. S. M. E., xii. 136) he gives a higher value, viz.,  $c = 1.12136 + 0.000488T$ .

L. A. Elleau and Wm. D. Ennis (*Jour. Franklin Inst.*, April, 1898) give the results of nine determinations, made between 0° and 20° C., which range from 0.983 to 1.056, averaging 1.0206. Von Strombeck (*Jour. Franklin Inst.*, Dec. 1890) found the specific heat between 62° and 31° C. to be 1.22876. Ludeking and Starr (*Am. Jour. Science*, iii, 45, 200) obtained 0.886. Prof. Wood deduced from thermodynamic equations  $c = 1.093$  at  $-34^{\circ}$  F. or  $-38^{\circ}$  C., and Ledoux in like manner finds  $c = 1.0058 + .003658t^{\circ}$  C. Elleau and Ennis give Ledoux's equation with a new constant derived from their experiments, thus  $c = 0.9834 + 0.003658t^{\circ}$  C.

**Specific Heat of Ammonia Vapor at the Saturation Point.** (Wood, Trans. A. S. M. E., x, 644.)—For the range of temperatures ordinarily used in engineering practice, the specific heat of saturated ammonia is negative, and the saturated vapor will condense with adiabatic expansion, and the liquid will evaporate with the compression of the vapor, and when all is vaporized will superheat.

Regnault (*Rel. des. Exp.*, ii, 162) gives for specific heat of ammonia-gas 0.50836. (Wood, Trans. A. S. M. E., xii, 133.)

**Properties of Brine used to absorb Refrigerating Effect of Ammonia.** (J. E. Denton, Trans. A. S. M. E., x, 799.)—A solution of Liverpool salt in well-water having a specific gravity of 1.17, or a weight per cubic foot of 73 lbs., will not sensibly thicken or congeal at 0° Fahrenheit.

The mean specific heat between 39° and 16° Fahr. was found by Denton to be 0.805. Brine of the same specific gravity has a specific heat of 0.805 at 65° Fahr., according to Naumann.

Naumann's values are as follows (*Lehr- und Handbuch der Thermochemie*, 1882):

Specific heat....	.791	.805*	.863	.895	.931	.962	.978
Specific gravity.	1.187	1.170	1.103	1.072	1.044	1.023	1.012

\* Interpolated.

**Chloride-of-calcium** solution has been used instead of brine. According to Naumann, a solution of 1.0255 sp. gr. has a specific heat of .957. A solution of 1.163 sp. gr. in the test reported in *Eng'g*, July 22, 1887, gave a specific heat of .827.

**ACTUAL PERFORMANCES OF ICE-MAKING MACHINES.**

The table given on page 996 is abridged from Denton, Jacobus, and Riesenberger's translation of Ledoux on Ice-making Machines. The following shows the class and size of the machines tested, referred to by letters in the table, with the names of the authorities:

Class of Machines.	Authority.	Dimensions of Compression-cylinder in inches.	
		Bore.	Stroke.

D. Closed cycle air .....	} Renwick & Jacobus.	10.	18.0
E. Ammonia dry-compression..		Denton.	12.0
F. Ammonia absorption .....	"		

**Performance of a 75-ton Ammonia Compression-machine.** (J. E. Denton, Trans. A. S. M. E., xii, 326.)—The machine had two single-acting compression cylinders 12" × 30", and one Corliss steam-cylinder, double-acting, 18" × 36". It was rated by the manufacturers as a 50-ton machine, but it showed 75 tons of ice-refrigerating effect per 24 hours during the test.

The most probable figures of performance in eight trials are as follows :

No. of Trial.	Ammonia Pressures, lbs. above Atmosphere.		Brine Temperatures, Degrees F.		Capacity Tons Refrigerating Effect per 24 hours.	Efficiency lbs. of Ice per lb. of Coal at 3 lbs. Coal per hour per H.P.	Water-consumption, gals. of Water per min. per ton of Capacity.	Ratio of Actual Weights of Ammonia circulated.	Ratio of Capacities.
	Con-densing	Suc-tion.	Inlet.	Outlet.					
1	151	28	36.76	28.86	70.3	22.60	0.80	1.0	1.0
8	161	27.5	36.36	28.45	70.1	22.27	1.09	1.0	1.0

2	135	15.7	4.62	3.22	27.2	13.20	1.25	2.59	2.57

The principal results in four tests are given in the table on page 998. The fuel economy under different conditions of operation is shown in the following table :

Condensing Pressure, lbs.	Suction-pressure, lbs.	Pounds of Ice-melting Effect with Engines—						B.T.U. per lb. of Steam with Engines—		
		Non-condensing.		Non-compound Condensing.		Compound Condensing.		Non-condensing.	Condensing.	Compound Condensing.
		Per lb. Coal.	Per lb. Steam.	Per lb. Coal.	Per lb. Steam.	Per lb. Coal.	Per lb. Steam.			
150	28	24	2.90	30	3.61	37.5	4.51	393	513	640
150	7	14	1.69	17.5	2.11	21.5	2.58	240	300	366
105	28	34.5	4.16	43	5.18	54	6.50	591	725	923
105	7	22	2.65	27.5	3.31	34.5	4.16	376	470	591

The non-condensing engine is assumed to require 25 lbs. of steam per horse-power per hour, the non-compound condensing 20 lbs., and the condensing 16 lbs., and the boiler efficiency is assumed at 8.3 lbs. of water per lb. coal under working conditions. The following conclusions were derived from the investigation :

1. The capacity of the machine is proportional, almost entirely, to the weight of ammonia circulated. This weight depends on the suction-pressure and the displacement of the compressor-pumps. The practical suction-pressures range from 7 lbs. above the atmosphere, with which a temperature of 0° F. can be produced, to 28 lbs. above the atmosphere, with which the temperatures of refrigeration are confined to about 28° F. At the lower pressure only about one half as much weight of ammonia can be circulated as at the upper pressure, the proportion being about in accordance with the ratios of the absolute pressures, 22 and 42 lbs. respectively. For each cubic foot of piston-displacement per minute a capacity of about one sixth of a ton of "refrigerating effect" per 24 hours can be produced at the lower pressure, and of about one third of a ton at the upper pressure. No other elements practically affect the capacity of a machine, provided the cooling-surface in the brine-tank or other space to be cooled is equal to about 36 sq. ft. per ton of capacity at 28 lbs. back pressure. For example, a difference of 100% in the rate of circulation of brine, while producing a proportional difference in the range of temperature of the latter, made no practical difference in capacity.

The brine-tank was  $10\frac{1}{2} \times 13 \times 10\frac{2}{3}$  ft., and contained 8000 lineal feet of 1-in. pipe as cooling-surface. The condensing-tank was  $12 \times 10 \times 10$  ft., and contained 5000 lineal feet of 1-in. pipe as cooling-surface.

2. The economy in coal-consumption depends mainly upon both the suction-pressures and condensing-pressures. Maximum economy, with a given type of engine, where water must be bought at average city prices, is obtained at 28 lbs. suction-pressure and about 150 lbs. condensing-pressure. Under these conditions, for a non-condensing steam-engine, consuming coal at the rate of 3 lbs. per hour per I.H.P. of steam-cylinders, 24 lbs. of ice-refrigerating effect are obtained per lb. of coal consumed. For the same condensing-pressure, and with 7 lbs. suction-pressure, which affords temperatures of 0° F., the possible economy falls to about 14 lbs. of "refrigerating effect" per lb. of coal consumed. The condensing-pressure is determined by the amount of condensing-water supplied to liquefy the ammonia in the condenser. If the latter is about 1 gallon per minute per ton of refrigerating effect per 24 hours, a condensing-pressure of 150 lbs. results, if the initial temperature of the water is about 56° F. Twenty-five per cent less water causes the condensing-pressure to increase to 190 lbs. The work of compression is thereby increased about 20%, and the resulting "economy" is reduced to about 18 lbs. of "ice effect" per lb. of coal at 28 lbs. suction-pressure and 11.5 at 7 lbs. If, on the other hand, the supply of water is made 3 gallons per minute, the condensing-pressure may be confined to about 105 lbs. The work of compression is thereby reduced about 25%, and a proportional increase of economy results. Minor alterations of economy depend on the initial temperature of the condensing-water and variations of latent heat, but these are confined within about 5% of the gross result, the main element of control being the work of compression, as affected by the back pressure and condensing-pressure, or both. If the steam-engine supplying the motive power may use a condenser to secure a vacuum, an increase of economy of 25% is available over the above figures, making the lbs. of "ice effect" per lb. of

coal for 150 lbs. condensing-pressure and 28 lbs. suction-pressure 30.0, and for 7 lbs. suction-pressure, 17.5. It is, however, impracticable to use a condenser in cities where water is bought. The latter must be practically free of cost to be available for this purpose. In this case it may be assumed that water will also be available for condensing the ammonia to obtain as low a condensing-pressure as about 100 lbs., and the economy of the refrigerating-machine becomes, for 28 lbs. back pressure, 43.0 lbs. of "ice effect" per lb. of coal, or for 7 lbs. back-pressure, 27.5 lbs. of ice effect per lb. of coal. If a compound condensing-engine can be used with a steam-consumption per hour per horse-power of 16 lbs. of water, the economy of the refrigerating-machine may be 25% higher than the figures last named, making for 28 lbs. back pressure a refrigerating effect of 54.0 lbs. per lb. of coal, and for 7 lbs. back pressure a refrigerating effect of 34.0 lbs. per lb. of coal.

\* Temperature of air at entrance and exit of expansion-cylinder.

† On a basis of 3 lbs. of coal per hour per H.P. of steam-cylinder of compression-machine and an evaporation of 11.1 lbs. of water per pound of combustible from and at 212° F. in the absorption-machine.

‡ Per cent of theoretical with no friction.

§ Loss due to heating during aspiration of gas in the compression-cylinder and to radiation and superheating at brine-tank.

¶ Actual, including resistance due to inlet and exit valves.

In class A, a German machine, the ice-melting capacity ranges from 46.29 to 16.14 lbs. of ice per pound of coal, according as the suction pressure varies from about 45 to 8 lbs. above the atmosphere, this pressure being the condition which mainly controls the economy of compression-machines. These results are equivalent to realizing from 72% to 57% of theoretically perfect performances. The higher per cents appear to occur with the higher suction-pressures, indicating a greater loss from cylinder-heating (a phenomenon the reverse of cylinder condensation in steam-engines), as the range of the temperature of the gas in the compression-cylinder is greater.

In E, an American compression-machine, operating on the "dry system," the percentage of theoretical effect realized ranges from 69.5% to 62.6%. The friction losses are higher for the American machine. The latter's higher efficiency may be attributed, therefore, to more perfect displacement.

The largest "ice-melting capacity" in the American machine is 24.16 lbs. This corresponds to the highest suction-pressures used in American practice for such refrigeration as is required in beer-storage cellars using the direct-expansion system. The conditions most nearly corresponding to American brewery practice in the German tests are those in line 5, which give an "ice-melting capacity" of 19.07 lbs.

For the manufacture of artificial ice, the conditions of practice are those of lines 3 and 4, and lines 25 and 26. In the former the condensing pressure used requires more expense for cooling water than is common in American practice. The ice-melting capacity is therefore greater in the German machine, being 22.03 and 16.14 lbs. against 17.55 and 14.52 for the American apparatus.

**CLASS B. Sulphur Dioxide or Pictet Machines.**—No records are available for determination of the "ice-melting capacity" of machines using pure sulphur dioxide. This fluid is in use in American machines, but in Europe it has given way to the "Pictet fluid," a mixture of about 97% of sulphur dioxide and 3% of carbonic acid. The presence of the carbonic acid affords a temperature about 14 Fahr. degrees lower than is obtained with pure sulphur dioxide at atmospheric pressure. The latent heat of this mixture has never been determined, but is assumed to be equal to that of pure sulphur dioxide.

For brewery refrigerating conditions, line 17, we have 26.24 lbs. "ice-melting capacity," and for ice-making conditions, line 13, the "ice-melting capacity" is 17.47 lbs. These figures are practically as economical as those for ammonia, the per cent of theoretical effect realized ranging from 65.4 to 57.8. At extremely low temperatures,  $-15^{\circ}$  Fahr., lines 14 and 18, the per cent realized is as low as 42.5.

**Cylinder-heating.**—In compression-machines employing volatile vapors the principal cause of the difference between the theoretical and the practical result is the heating of the ammonia, by the warm cylinder walls, during its entrance into the compressor, thereby expanding it, so that to compress a pound of ammonia a greater number of revolutions must be made by the compressing-pumps than corresponds to the density of the ammonia-gas as it issues from the brine-tank.

**Tests of Ammonia Absorption-machine** used in storage-warehouses under approaches to the New York and Brooklyn Bridge. (*Eng'g*, July 22, 1887.)—The circulated fluid consisted of a solution of chloride of calcium of 1.163 sp. gr. Its specific heat was found to be .827.

The efficiency of the apparatus for 24 hours was found by taking the product of the cubic feet of brine circulating through the pipes by the average difference in temperature in the ingoing and outgoing currents, as observed at frequent intervals by the specific heat of the brine (.827) and its weight per cubic foot (73.48). The final product, applying all allowances for corrections from various causes, amounted to 6,218,816 heat-units as the amount abstracted in 24 hours, equal to the melting of 43,565 lbs. of ice in the same time.

The theoretical heating-power of the coal used in 24 hours was 27,000,000 heat-units; hence the efficiency of the apparatus was 23%. This is equivalent to an ice-melting effect of 16.1 lbs. per lb. of coal having a heating value of 10,000 B.T.U. per lb.

A test of a 35-ton absorption-machine in New Haven, Conn., by Prof. Denton (*Trans. A. S. M. E.*, x. 792), gave an ice-melting effect of 20.1 lbs. per lb. of coal on a basis of boiler economy equivalent to 3 lbs. of steam per I.H.P. in a good non-condensing steam-engine. The ammonia was worked between 138 and 23 lbs. pressure above the atmosphere.

**Means for Applying the Cold.** (M. C. Bannister, Liverpool Eng'g Soc'y, 1890.)—The most useful means for applying the cold to various uses is a saturated solution of brine or chloride of magnesium, which remains liquid at 5° Fahr.\* The brine is first cooled by being circulated in contact with the refrigerator-tubes, and then distributed through coils of pipes, arranged either in the substances requiring a reduction of temperature, or in the cold stores or rooms prepared for them; the air coming in contact with the cold tubes is immediately chilled, and the moisture in the air deposited on the pipes. It then falls, making room for warmer air, and so circulates until the whole room is at the temperature of the brine in the pipes.

In a recent arrangement for refrigerating made by the Linde British Refrigeration Co., the cold brine is circulated through a shallow trough, in which revolve a number of shafts, each geared together, and driven by mechanical means. On the shafts are fixed a number of wrought-iron disks, partly immersed in the brine, which cool them down to the brine temperature as they revolve; over these disks a rapid circulation of air is passed by a fan, being cooled by contact with the plates; then it is led into the chambers requiring refrigeration, from which it is again drawn by the same fan; thus all moisture and impurities are removed from the chambers, and deposited in the brine, producing the most perfect antiseptic atmosphere yet invented for cold storing; while the maximum efficiency of the brine temperature was always available, the brine being periodically concentrated by suitable arrangements.

*Air has also been used* as the circulating medium. The ammonia-pipes refrigerate the air in a cooling-chamber, and large wooden conduits are used to convey it to and return it from the rooms to be cooled. An advantage of this system is that by it a room may be refrigerated more quickly than by brine-coils. The returning air deposits its moisture in the form of snow on the ammonia-pipes, which is removed by mechanical brushes.

**ARTIFICIAL ICE-MANUFACTURE.**

Under summer conditions, with condensing water at 70°, artificial ice-machines use ammonia at about 190 lbs. above the atmosphere condenser-pressure, and 15 lbs. suction-pressure.

In a compression type of machine the useful circulation of ammonia, allowing for the effect of cylinder-heating, is about 13 lbs. per hour per indicated horse-power of the steam cylinder. This weight of ammonia produces about 32 lbs. of ice at 15° from water at 70°. If the ice is made from distilled water, as in the "can system," the amount of the latter supplied by the boilers is about 33% greater than the weight of ice obtained. This excess represents steam escaping to the atmosphere, from the re-boiler and steam-condenser, to purify the distilled water, or free it from air; also, the loss through leaks and drips, and loss by melting of the ice in extracting it from the cans. The total steam consumed per horse-power is, therefore, about  $32 \times 1.33 = 43.0$  lbs. About 7.0 lbs. of this covers the steam-consumption of the steam-engines driving the brine circulating-pumps, the several

# 1000 ICE-MAKING OR REFRIGERATING MACHINES.

cold-water pumps, and leakage, drips, etc. Consequently, the main steam-engine must consume 36 lbs. of steam per hour per I.H.P., or else live steam must be condensed to supply the required amount of distilled water. There is, therefore, nothing to be gained by using steam at high rates of expansion in the steam-engines, in making artificial ice from distilled water. If the cooling water for the ammonia-coils and steam-condenser is not too hard for use in the boilers, it may enter the latter at about 175° F., by restricting the quantity to 1½ gallons per minute per ton of ice. With good coal 8½ lbs. of feed-water may then be evaporated, on the average, per lb. of coal.

The ice made per pound of coal will then be  $32 \div (43.0 \div 8.5) = 6.0$  lbs. This corresponds with the results of average practice.

If ice is manufactured by the "plate system," no distilled water is used for freezing. Hence the water evaporated by the boilers may be reduced to the amount which will drive the steam-motors, and the latter may use steam expansively to any extent consistent with the power required to compress the ammonia, operate the feed and filter pumps, and the hoisting machinery. The latter may require about 15% of the power needed for compressing the ammonia.

If a compound condensing steam-engine is used for driving the compressors, the steam per indicated steam horse-power, or per 32 lbs. of net ice, may be 14 lbs. per hour. The other motors at 50 lbs. of steam per horse-power will use 7.5 lbs. per hour, making the total consumption per steam horse-power of the compressor 21.5 lbs. Taking the evaporation at 8 lbs., the feed-water temperature being limited to about 110°, the coal per horse-power is 2.7 lbs. per hour. The net ice per lb. of coal is then about  $32 \div 2.7 = 11.8$  lbs. The best results with "plate-system" plants, using a compound steam-engine, have thus far afforded about 10½ lbs. of ice per lb. of coal.

In the "plate system" the ice gradually forms, in from 8 to 10 days, to a thickness of about 14 inches, on the hollow plates, 10 × 14 feet in area, in which the cooling fluid circulates.

In the "can system" the water is frozen in blocks weighing about 300 lbs. each, and the freezing is completed in from 40 to 48 hours. The freezing-tank area occupied by the "plate system" is, therefore, about twelve times, and the cubic contents about four times as much as required in the "can system."

The investment for the "plate" is about one-third greater than for the "can" system. In the latter system ice is being drawn throughout the 24 hours, and the hoisting is done by hand tackle. Some "can" plants are equipped with pneumatic hoists and on large hoists electric cranes are used to advantage. In the "plate system" the entire daily product is drawn, cut, and stored in a few hours, the hoisting being performed by power. The distribution of cost is as follows for the two systems, taking the cost for the "can" or distilled-water system as 100, which represents an actual cost of about \$1.25 per net ton:

	Can System.	Plate System.
Hoisting and storing ice. ....	14.2	2.8
Engineers, firemen, and coal-passer. ....	15.0	13.9
Coal at \$3.50 per gross ton.....	42.2	20.0
Water pumped directly from a natural source at 5 cts. per 1000 cubic feet.....	1.3	2.6
Interest and depreciation at 10%... ..	24.6	32.7
Repairs.....	2.7	3.4
	100.00	75.4

A compound condensing engine is assumed to be used by the "plate system."

**Test of the New York Hygeia Ice-making Plant.**—(By Messrs. Hupfel, Griswold, and Mackenzie; *Stevens Indicator*, Jan. 1894.)

The final results of the tests were as follows:

Net ice made per pound of coal, in pounds.....	7.12
Pounds of net ice per hour per horse-power.....	37.8
Net ice manufactured per day (12 hours) in tons.....	97
Av. pressure of ammonia-gas at condenser, lbs. per sq. in. ab. atmos.	135.2
Average back pressure of amm.-gas, lbs. per sq. in. above atmos....	15.8
Average temperature of brine in freezing-tanks, degrees F.....	19 7
Total number of cans filled per week ... ..	4389
Ratio of cooling-surface of coils in brine-tank to can-surface.....	7 to 10

Ratio of brine in tanks to water in cans .....	1 to 1.2
Ratio of circulating water at condensers to distilled water.....	26 to 1
Pounds of water evaporated at boilers per pound of coal.....	8.085
Total horse-power developed by compressor-engines....	444
Percentage of ice lost in removing from cans.....	2.2

## APPROXIMATE DIVISION OF STEAM IN PER CENTS OF TOTAL AMOUNT.

Compressor-engines .....	60.1
Live steam admitted directly to condensers....	19.7
Steam for pumps, agitator, and elevator engines.....,	7.6
Live steam for reboiling distilled water....	6.5
Steam for blowers furnishing draught at boilers.....	5.6
Sprinklers for removing ice from cans.....	0.5

The precautions taken to insure the purity of the ice are thus described:

The water which finally leaves the condenser is the accumulation of the exhausts from the various pumps and engines, together with an amount of live steam injected into it directly from the boilers. This last quantity is used to make up any deficit in the amount of water necessary to supply the ice-cans. This water on leaving the condensers is violently reboiled, and afterwards cooled by running through a coil surface-cooler. It then passes through an oil-separator, after which it runs through three charcoal-filters and deodorizers, placed in series and containing 28 feet of charcoal. It next passes into the supply-tank in which there is an electrical attachment for detecting salt. Nitrate-of-silver tests are also made for salt daily. From this tank it is fed to the ice-caus, which are carefully covered so that the water cannot possibly receive any impurities.

## MARINE ENGINEERING.

**Rules for Measuring Dimensions and Obtaining Tonnage of Vessels.** (Record of American & Foreign Shipping. American Bureau of Shipping, N. Y. 1890.)—The dimensions to be measured as follows:

I. Length, *L*.—From the fore side of stem to the after side of stern-post measured at middle line on the upper deck of all vessels, except those having a continuous hurricane-deck extending right fore and aft, in which the length is to be measured on the range of deck immediately below the hurricane-deck.

Vessels having clipper heads, raking forward, or receding stems, or raking stern-posts, the length to be the distance of the fore side of stem from aft-side of stern-post at the deep-load water-line measured at middle line. (The inner or propeller-post to be taken as stern-post in screw-steamers.)

II. Breadth, *B*.—To be measured over the widest frame at its widest part; in other words, the moulded breadth.

III. Depth, *D*.—To be measured at the dead-flat frame and at middle line of vessel. It shall be the distance from the top of floor-plate to the upper side of upper deck-beam in all vessels except those having a continuous hurricane-deck, extending right fore and aft, and not intended for the American coasting trade, in which the depth is to be the distance from top of floor-plate to midway between top of hurricane deck-beam and the top of deck-beam of the deck immediately below hurricane-deck.

In vessels fitted with a continuous hurricane deck, extending right fore and aft and intended for the American coasting trade, the depth is to be the distance from top of floor-plate to top of deck-beam of deck immediately below hurricane-deck.

**Rule for Obtaining Tonnage.**—Multiply together the length, breadth, and depth, and their product by .75; divide the last product by 100; the quotient will be the tonnage. 
$$\frac{L \times B \times D \times 75}{100} = \text{tonnage.}$$

**The U. S. Custom-house Tonnage Law, May 6, 1864,** provides that "the register tonnage of a vessel shall be her entire internal cubic capacity in tons of 100 cubic feet each." This measurement includes all the space between upper decks, however many there may be. Explicit directions for making the measurements are given in the law.

**The Displacement of a Vessel** (measured in tons of 2240 lbs.) is the weight of the volume of water which it displaces. For sea-water it is equal to the volume of the vessel beneath the water-line, in cubic feet, divided by 35, which figure is the number of cubic feet of sea-water at 60°

F. in a ton of 2240 lbs. For fresh water the divisor is 35.93. The U. S. register tonnage will equal the displacement when the entire internal cubic capacity bears to the displacement the ratio of 100 to 35.

The displacement or gross tonnage is sometimes approximately estimated as follows: Let  $L$  denote the length in feet of the boat,  $B$  its extreme breadth in feet, and  $D$  the mean draught in feet; the product of these three dimensions will give the volume of a parallelopipedon in cubic feet. Putting  $V$  for this volume, we have  $V = L \times B \times D$ .

The volume of displacement may then be expressed as a percentage of the volume  $V$ , known as the "block coefficient." This percentage varies for different classes of ships. In racing yachts with very deep keels it varies from 22 to 33; in modern merchantmen from 55 to 75; for ordinary small boats probably 50 will give a fair estimate. The volume of displacement in cubic feet divided by 35 gives the displacement in tons.

**Coefficient of Fineness.**—A term used to express the relation between the displacement of a ship and the volume of a rectangular prism or box whose lineal dimensions are the length, breadth, and draught of the ship.

Coefficient of fineness =  $\frac{D \times 35}{L \times B \times W}$ ;  $D$  being the displacement in tons of 35 cubic feet of sea-water to the ton,  $L$  the length between perpendiculars,  $B$  the extreme breadth of beam, and  $W$  the mean draught of water, all in feet.

**Coefficient of Water-lines.**—An expression of the relation of the displacement to the volume of the prism whose section equals the midship section of the ship, and length equal to the length of the ship.

Coefficient of water-lines =  $\frac{D \times 35}{\text{area of immersed water section} \times L}$ . Seaton gives the following values:

	Coefficient of Fineness.	Coefficient of Water-lines.
Finely-shaped ships.....	0.55	0.63
Fairly-shaped ships.....	0.61	0.67
Ordinary merchant steamers for speeds of 10 to 11 knots.....	0.65	0.72
Cargo steamers, 9 to 10 knots.....	0.70	0.76
Modern cargo steamers of large size.....	0.78	0.83

**Resistance of Ships.**—The resistance of a ship passing through water may vary from a number of causes, as speed, form of body, displacement, midship dimensions, character of wetted surface, fineness of lines, etc. The resistance of the water is twofold: 1st. That due to the displacement of the water at the bow and its replacement at the stern, with the consequent formation of waves. 2d. The friction between the wetted surface of the ship and the water, known as skin resistance. A common approximate formula for resistance of vessels is

$$\text{Resistance} = \text{speed}^2 \times \sqrt[3]{\text{displacement}^2} \times \text{a constant, or } R = S^2 D^{\frac{2}{3}} \times C.$$

If  $D$  = displacement in pounds,  $S$  = speed in feet per minute,  $R$  = resistance in foot-pounds per minute,  $R = CS^2 D^{\frac{2}{3}}$ . The work done in overcoming the resistance through a distance equal to  $S$  is  $R \times S = CS^3 D^{\frac{2}{3}}$ ; and if  $E$  is the efficiency of the propeller and machinery combined, the indicated

$$\text{horse-power I.H.P.} = \frac{CS^3 D^{\frac{2}{3}}}{E \times 33,000}.$$

If  $S$  = speed in knots,  $D$  = displacement in tons, and  $C$  a constant which includes all the constants for form of vessel, efficiency of mechanism, etc.,

$$\text{I.H.P.} = \frac{S^3 D^{\frac{2}{3}}}{C}.$$

The wetted surface varies as the cube root of the square of the displacement; thus, let  $L$  be the length of edge of a cube just immersed, whose displacement is  $D$  and wetted surface  $W$ . Then  $D = L^3$  or  $L = \sqrt[3]{D}$ , and  $W = 5 \times L^2 = 5 \times (\sqrt[3]{D})^2$ . That is,  $W$  varies as  $D^{\frac{2}{3}}$ .

quantity in the parenthesis, which is known as the "coefficient of augmentation." The last term of the coefficient may be neglected in calculating the resistance of ships as too small to be practically important. In applying the formula, the mean of the squares of the sines of the angles of maximum obliquity of the water-lines is to be taken for  $\sin^2 \theta$ , and the rule will then read thus:

To obtain the resistance of a ship of good form, in pounds, multiply the length in feet by the mean immersed girth and by the coefficient of augmentation, and then take the product of this "augmented surface," as Rankine termed it, by the square of the speed in knots, and by the proper constant coefficient selected from the following:

- For clean painted vessels, iron hulls.....  $A = .01$
- For clean coppered vessels.....  $A = .009$  to  $.008$
- For moderately rough iron vessels.....  $A = .011 +$

The net, or effective, horse-power demanded will be quite closely obtained by multiplying the resistance calculated, as above, by the speed in knots and dividing by 326. The gross, or indicated, power is obtained by multiplying the last quantity by the reciprocal of the efficiency of the machinery and propeller, which usually should be about 0.6. Rankine uses as a divisor in this case 200 to 260.

The form of the vessel, even when designed by skilful and experienced naval architects, will often vary to such an extent as to cause the above constant coefficients to vary somewhat; and the range of variation with good forms is found to be from 0.8 to 1.5 the figures given.

For well-shaped iron vessels, an approximate formula for the horse-power required is  $H.P. = \frac{SV^3}{20,000}$ , in which  $S$  is the "augmented surface." The ex-

pression  $\frac{SV^3}{H.P.}$  has been called by Rankine the *coefficient of propulsion*. In the Hudson River steamer "Mary Powell," according to Thurston, this coefficient was as high as 23,500.

The expression  $\frac{D^{\frac{2}{3}}V^3}{H.P.}$  has been called the *locomotive performance*. (See Rankine's Treatise on Shipbuilding, 1864; Thurston's Manual of the Steam-engine, part ii. p. 16; also paper by F. T. Bowles, U.S.N., Proc. U. S. Naval Institute, 1883.)

Rankine's method for calculating the resistance is said by Seaton to give more accurate and reliable results than those obtained by the older rules, but it is criticised as being difficult and inconvenient of application.

**Dr. Kirk's Method.**—This method is generally used on the Clyde.

The general idea proposed by Dr. Kirk is to reduce all ships to so definite and simple a form that they may be easily compared; and the magnitude of certain features of this form shall determine the suitability of the ship for speed, etc.

The form consists of a middle body, which is a rectangular parallelopiped, and fore body and after body, prisms having isosceles triangles for bases, as shown in Fig. 168.

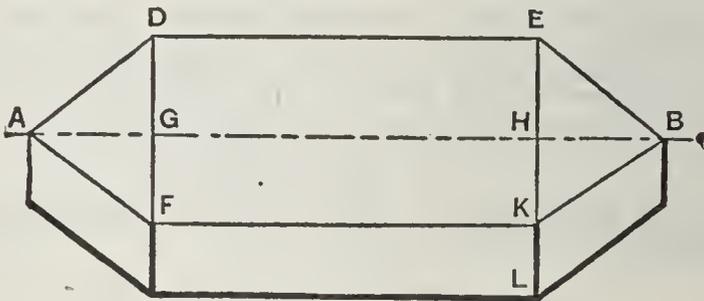

FIG. 168.

This is called a block model, and is such that its length is equal to that of the ship, the depth is equal to the mean draught, the capacity equal to the displacement volume, and its area of section equal to the area of im-

mersed midship section. The dimensions of the block model may be obtained as follows:

Let  $AG = HB =$  length of fore- or after-body  $= F$ ;  
 $GH =$  length of middle body  $= M$ ;  
 $KL =$  mean draught  $= H$ ;  
 $EK = \frac{\text{area of immersed midship section}}{KL} = B$ .

Volume of block  $= (F + M) \times B \times H$ ;  
 Midship section  $= B \times H$ ;  
 Displacement in tons  $=$  volume in cubic ft.  $\div 35$ .

$AH = AG + GH = F + M =$  displacement  $\times 35 \div (B \times H)$ .

The wetted surface of the block is nearly equal to that of the ship of the same length, beam and draught; usually 2% to 5% greater. In exceedingly fine hollow-line ships it may be 8% greater.

Area of bottom of block  $= (F + M) \times B$ ;  
 Area of sides  $= 2M \times H$ .

Area of sides of ends  $= 4\sqrt{F^2 + \left(\frac{B}{2}\right)^2} \times H$ ;

Tangent of half angle of entrance  $= \frac{\frac{1}{2}B}{F} = \frac{B}{2F}$ .

From this, by a table of natural tangents, the angle of entrance may be obtained:

	Angle of Entrance of the Block Model.	Fore-body in parts of length.
Ocean-going steamers, 14 knots and upward.	18° to 15°	.3 to .36
“ “ 12 to 14 knots.....	21 to 18	.26 to .3
“ cargo steamers, 10 to 12 knots..	30 to 22	.22 to .26

**E. R. Mumford's Method of Calculating Wetted Surfaces** is given in a paper by Archibald Denny, *Eng'g*, Sept. 21, 1894. The following is his formula, which gives closely accurate results for medium draughts, beams, and finenesses:

$S = (L \times D \times 1.7) + (L \times B \times C)$ ,

in which  $S =$  wetted surface in square feet;  
 $L =$  length between perpendiculars in feet;  
 $D =$  middle draught in feet;  
 $B =$  beam in feet;  
 $C =$  block coefficient.

The formula may also be expressed in the form  $S = L(1.7D + BC)$ .

In the case of twin-screw ships having projecting shaft-casings, or in the case of a ship having a deep keel or bilge keels, an addition must be made for such projections. The formula gives results which are in general much more accurate than those obtained by Kirk's method. It underestimates the surface when the beam, draught, or block coefficients are excessive; but the error is small except in the case of abnormal forms, such as stern-wheel steamers having very excessive beams (nearly one fourth the length), and also very full block coefficients. The formula gives a surface about 6% too small for such forms.

**To Find the Indicated Horse-power from the Wetted Surface.** (Seaton.)—In ordinary cases the horse-power per 100 feet of wetted surface may be found by assuming that the rate for a speed of 10 knots is 5, and that the quantity varies as the cube of the speed. For example: To find the number of I.H.P. necessary to drive a ship at a speed of 15 knots, having a wetted skin of block model of 16,200 square feet:

The rate per 100 feet  $= (15/10)^3 \times 5 = 16.875$ .  
 Then I.H.P. required  $= 16.875 \times 162 = 2734$ .

When the ship is exceptionally well-proportioned, the bottom quite clean, and the efficiency of the machinery high, as low a rate as 4 I.H.P. per 100 feet of wetted skin of block model may be allowed

The gross indicated horse-power includes the power necessary to overcome the friction and other resistance of the engine itself and the shafting, and also the power lost in the propellor. In other words, I.H.P. is no measure of the resistance of the ship, and can only be relied on as a means of deciding the size of engines for speed, so long as the efficiency of the engine and propellor is known definitely, or so long as similar engines and propellers are employed in ships to be compared. The former is difficult to obtain, and it is nearly impossible in practice to know how much of the power shown in the cylinders is employed usefully in overcoming the resistance of the ship. The following example is given to show the variation in the efficiency of propellers:

	Knots.	I.H.P.
H.M.S. "Amazon," with a 4-bladed screw, gave.....	12.064	with 1940
H.M.S. "Amazon," with a 2-bladed screw, increased pitch, and less revolutions per minute.....	12.396	" 1663
H.M.S. "Iris," with a 4-bladed screw.....	16.577	" 7503
H.M.S. "Iris," with 2-bladed screw, increased pitch, less revolutions per knot.....	18.587	" 7556

**Relative Horse-power Required for Different Speeds of Vessels.** (Horse-power for 10 knots = 1.)—The horse-power is taken usually to vary as the cube of the speed, but in different vessels and at different speeds it may vary from the 2.8 power to the 3.5 power, depending upon the lines of the vessel and upon the efficiency of the engines, the propeller, etc.

EXAMPLE IN USE OF THE TABLE.—A certain vessel makes 14 knots speed with 587 I.H.P. and 16 knots with 900 I.H.P. What I.H.P. will be required at 18 knots, the rate of increase of horse-power with increase of speed remaining constant? The first step is to find the rate of increase, thus:  $14^x : 16^x :: 587 : 900$ .

$$x \log 16 - x \log 14 = \log 900 - \log 587;$$

$$x(0.204120 - 0.146128) = 2.954243 - 2.768638,$$

whence  $x$  (the exponent of  $S$  in formula  $H.P. \propto S^x$ ) = 3.2.

From the table, for  $S^{3.2}$  and 16 knots, the I.H.P. is 4.5 times the I.H.P. at 10 knots,  $\therefore$  H.P. at 10 knots =  $900 \div 4.5 = 200$ .

From the table, for  $S^{3.2}$  and 18 knots, the I.H.P. is 6.559 times the I.H.P. at 10 knots;  $\therefore$  H.P. at 18 knots =  $200 \times 6.559 = 1312$  H.P.

**Resistance per Horse-power for Different Speeds.** (One horse-power = 33,000 lbs. resistance overcome through 1 ft. in 1 min.)—The resistances per horse-power for various speeds are as follows: For a speed of 1 knot, or 6080 feet per hour =  $101\frac{1}{3}$  ft. per min.,  $33,000 \div 101\frac{1}{3} = 325.658$  lbs. per horse-power; and for any other speed 325.658 lbs. divided by the speed in knots; or for

1 knot	325.66 lbs.	6 knots	54.28 lbs.	11 knots	29.61 lbs.	16 knots	20.35 lbs.

The figures for I.H.P. are "round." The "Medusa's" figures for 20 knots are from trial on Stokes Bay, and show the retarding effect of shallow water. The figures for the other ships for 20 knots are estimated for deep water.

More accurate methods than those above given for estimating the horse-power required for any proposed ship are: 1. Estimations calculated from the results of trials of "similar" vessels driven at "corresponding" speeds; "similar" vessels being those that have the same ratio of length to breadth and to draught, and the same coefficient of fineness, and "corresponding" speeds those which are proportional to the square roots of the lengths of the respective vessels. Froude found that the resistances of such vessels varied almost exactly as wetted surface × (speed)<sup>2</sup>.

2. The method employed by the British Admiralty and by some Clyde shipbuilders, viz., ascertaining the resistance of a model of the vessel, 12 to 20 ft. long, in a tank, and calculating the power from the results obtained.

**Speed on Canals.**—A great loss of speed occurs when a steam-vessel passes from open water into a more or less restricted channel. The average speed of vessels in the Suez Canal in 1882 was only 5½ statute miles per hour. (Eng'g, Feb. 15, 1884, p. 139.)

**Estimated Displacement, Horse-power, etc.**—The table on the next page, calculated by the author, will be found convenient for making approximate estimates.

The figures in 7th column are calculated by the formula  $H.P. = S^3 D^{\frac{2}{3}} \div c$ , in which  $c = 200$  for vessels under 200 ft. long when  $C = .65$ , and 210 when  $C = .55$ ;  $c = 200$  for vessels 200 to 400 ft. long when  $C = .75$ , 220 when  $C = .65$ , 240 when  $C = .55$ ;  $c = 230$  for vessels over 400 ft. long when  $C = .75$ , 250 when  $C = .65$ , 260 when  $C = .55$ .

The figures in the 8th column are based on 5 H.P. per 100 sq. ft. of wetted surface.

The diameters of screw in the 9th column are from formula  $D = 3.31 \sqrt[5]{I.H.P.}$ , and in the 10th column from formula  $D = 2.71 \sqrt[5]{I.H.P.}$ .

To find the diameter of screw for any other speed than 10 knots, revolutions being 100 per minute, multiply the diameter given in the table by the 5th root of the cube of the given speed ÷ 10. For any other revolutions per minute than 100, divide by the revolutions and multiply by 100.

To find the approximate horse-power for any other speed than 10 knots, multiply the horse-power given in the table by the cube of the ratio of the given speed to 10, or by the relative figure from table on p. 1006.

$$D = \text{diameter of propeller} = K \sqrt{\frac{\text{I.H.P.}}{\left(\frac{P \times R}{100}\right)^3}}, K \text{ being a coefficient given}$$

in the table below. If  $K = 20, D = 20000 \sqrt{\frac{\text{I.H.P.}}{(P \times R)^3}}$ .

Total developed area of blades =  $C \sqrt{\frac{\text{I.H.P.}}{R}}$ , in which  $C$  is a coefficient to be taken from the table.

Another formula for pitch, given in Seaton's Marine Engineering, is  $P = \frac{C}{R} \sqrt[3]{\frac{\text{I.H.P.}}{D^2}}$ , in which  $C = 737$  for ordinary vessels, and 660 for slow-speed cargo vessels with full lines.

Thickness of blade at root =  $\sqrt{\frac{d^3}{nb}} \times k$ , in which  $d$  = diameter of tail shaft in inches,  $n$  = number of blades,  $b$  = breadth of blade in inches where it joins the boss, measured parallel to the shaft axis;  $k = 4$  for cast iron, 1.5 for cast steel, 2 for gun-metal, 1.5 for high-class bronze.

Thickness of blade at tip: Cast iron .04 $D$  + .4 in.; cast steel .03 $D$  + .4 in.; gun-metal .03 $D$  + .2 in.; high-class bronze .02 $D$  + .3 in., where  $D$  = diameter of propeller in feet.

**Propeller Coefficients.**

Description of Vessel.	Approximate Speed in knots.	Number of Screws.	Number of Blades per Screw.	Values of K.	Values of C.	Usual Material of Blades.
Bluff cargo boats.....	8-10	One	4	17 -17.5	19 -17.5	Cast iron
Cargo, moderate lines...	10-13	"	4	18 -19	17 -15.5	" "
Pass. and mail, fine lines.	13-17	"	4	19.5-20.5	15 -13	C. I. or S.
" " " " "	13-17	Twin	4	20.5-21.5	14.5-12.5	" "
" " " very fine.	17-22	One	4	21 -22	12.5-11	G. M. or B
" " " " "	17-22	Twin	3	22 -23	10.5- 9	" " "
Naval vessels, " "	16-22	"	4	21 -22.5	11.5-10.5	" " "
" " " " "	16-22	"	3	22 -23.5	8.5- 7	" " "

C. I., cast iron; G. M., gun-metal; B., bronze; S., steel; F. S., forged steel.

From the formulæ  $D = 20000 \sqrt{\frac{\text{I.H.P.}}{(P \times R)^3}}$  and  $P = \frac{737}{R} \sqrt[3]{\frac{\text{I.H.P.}}{D^2}}$ , if  $P = D$

and  $R = 100$ , we obtain  $D = \sqrt[5]{400 \times \text{I.H.P.}} = 3.31 \sqrt[5]{\text{I.H.P.}}$

If  $P = 1.4D$  and  $R = 100$ , then  $D = \sqrt[5]{145.8 \times \text{I.H.P.}} = 2.71 \sqrt[5]{\text{I.H.P.}}$

From these two formulæ the figures for diameter of screw in the table on page 1009 have been calculated. They may be used as rough approximations to the correct diameter of screw for any given horse-power, for a speed of 10 knots and 100 revolutions per minute.

For any other number of revolutions per minute multiply the figures in the table by 100 and divide by the given number of revolutions. For any other speed than 10 knots, since the I.H.P. varies approximately as the cube of the speed, and the diameter of the screw as the 5th root of the I.H.P., multiply the diameter given for 10 knots by the 5th root of the cube of one tenth of the given speed. Or, multiply by the following factors:

For speed of knots:

	4	5	6	7	8	9	11	12	13	14	15	16
$\sqrt[5]{(S + 10)^3}$												
	= .577	.660	.736	.807	.875	.939	1.059	1.116	1.170	1.224	1.275	1.327

Speed:

	17	18	19	20	21	22	23	24	25	26	27	28
$\sqrt[5]{(S + 10)^2}$	1.375	1.423	1.470	1.515	1.561	1.605	1.648	1.691	1.733	1.774	1.815	1.855

For more accurate determinations of diameter and pitch of screw, the formulæ and coefficients given by Seaton, quoted above, should be used.

**Efficiency of the Propeller.**—According to Rankine, if the slip of the water be  $s$ , its weight  $W$ , the resistance  $R$ , and the speed of the ship  $v$ ,

$$R = \frac{Ws}{g}; \quad Rv = \frac{Wsv}{g}.$$

This impelling action must, to secure maximum efficiency of propeller, be effected by an instrument which takes hold of the fluid without shock or disturbance of the surrounding mass, and, by a steady acceleration, gives it the required final velocity of discharge. The velocity of the propeller overcoming the resistance  $R$  would then be

$$\frac{v + (v + s)}{2} = v + \frac{s}{2};$$

and the work performed would be

$$R\left(v + \frac{s}{2}\right) = \frac{Wvs}{g} + \frac{Ws^2}{2g},$$

the first of the last two terms being useful, the second the minimum lost work; the latter being the wasted energy of the water thrown backward. The efficiency is

$$E = v \div \left(v + \frac{s}{2}\right);$$

and this is the limit attainable with a perfect propelling instrument, which limit is approached the more nearly as the conditions above prescribed are the more nearly fulfilled. The efficiency of the propelling instrument is probably rarely much above 0.60, and never above 0.80.

In designing the screw-propeller, as was shown by Dr. Froude, the best angle for the surface is that of 45° with the plane of the disk; but as all parts of the blade cannot be given the same angle, it should, where practicable, be so proportioned that the "pitch-angle at the centre of effort" should be made 45°. The maximum possible efficiency is then, according to Froude, 77%.

In order that the water should be taken on without shock and discharged with maximum backward velocity, the screw must have an axially increasing pitch.

The true screw is by far the more usual form of propeller, in all steamers, both merchant and naval. (Thurston, Manual of the Steam-engine, part ii., p. 176.)

The combined efficiency of screw, shaft, engine, etc., is generally taken at 50%. In some cases it may reach 60% or 65%. Rankine takes the effective H.P. to equal the I.H.P. ÷ 1.63.

**Pitch-ratio and Slip for Screws of Standard Form.**

Pitch-ratio.	Real Slip of Screw.	Pitch-ratio.	Real Slip of Screw.
.8	15.55	1.7	21.3
.9	16.22	1.8	21.8
1.0	16.88	1.9	22.4
1.1	17.55	2.0	22.9
1.2	18.2	2.1	23.5
1.3	18.8	2.2	24.0
1.4	19.5	2.3	24.5
1.5	20.1	2.4	25.0
1.6	20.7	2.5	25.4

**Results of Recent Researches** on the efficiency of screw-propellers are summarized by S. W. Barnaby, in a paper read before section G of the Engineering Congress, Chicago, 1893. He states that the following general principles have been established:

(a) There is a definite amount of real slip at which, and at which only, maximum efficiency can be obtained with a screw of any given type, and this amount varies with the pitch-ratio. The slip-ratio proper to a given ratio of pitch to diameter has been discovered and tabulated for a screw of a standard type, as below (see table on page 1012):

(b) Screws of large pitch-ratio, besides being less efficient in themselves, add to the resistance of the hull by an amount bearing some proportion to their distance from it, and to the amount of rotation left in the race.

(c) The best pitch-ratio lies probably between 1.1 and 1.5.

(d) The fuller the lines of the vessel, the less the pitch-ratio should be.

(e) Coarse-pitched screws should be placed further from the stern than fine-pitched ones.

(f) Apparent negative slip is a natural result of abnormal proportions of propellers.

(g) Three blades are to be preferred for high-speed vessels, but when the diameter is unduly restricted, four or even more may be advantageously employed.

(h) An efficient form of blade is an ellipse having a minor axis equal to four tenths the major axis.

(i) The pitch of wide-bladed screws should increase from forward to aft, but a uniform pitch gives satisfactory results when the blades are narrow, and the amount of the pitch variation should be a function of the width of the blade.

(j) A considerable inclination of screw-shaft produces vibration, and with right-handed twin-screws turning outwards, if the shafts are inclined at all, it should be upwards and outwards from the propellers.

For results of experiments with screw-propellers, see F. C. Marshall, Proc. Inst. M. E. 1881; R. E. Froude, Trans. Institution of Naval Architects, 1886; G. A. Calvert, Trans. Institution of Naval Architects 1887; and S. W. Barnaby, Proc. Inst. Civil Eng'rs 1890, vol. cii.

One of the most important results deduced from experiments on model screws is that they appear to have practically equal efficiencies throughout a wide range both in pitch-ratio and in surface-ratio; so that great latitude is left to the designer in regard to the form of the propeller. Another important feature is that, although these experiments are not a direct guide to the selection of the most efficient propeller for a particular ship, they supply the means of analyzing the performances of screws fitted to vessels, and of thus indirectly determining what are likely to be the best dimensions of screw for a vessel of a class whose results are known. Thus a great advance has been made on the old method of trial upon the ship itself, which was the origin of almost every conceivable erroneous view respecting the screw-propeller. (Proc. Inst. M. E., July, 1891.)

## THE PADDLE-WHEEL.

**Paddle-wheels with Radial Floats.** (Seaton's Marine Engineering.)—The effective diameter of a radial wheel is usually taken from the centres of opposite floats; but it is difficult to say what is absolutely that diameter, as much depends on the form of float, the amount of dip, and the waves set in motion by the wheel. The slip of a radial wheel is from 15 to 30 per cent, depending on the size of float.

$$\text{Area of one float} = \frac{\text{I.H.P.}}{D} \times C.$$

$D$  is the effective diameter in feet, and  $C$  is a multiplier, varying from 0.25 in tugs to 0.175 in fast-running light steamers.

The breadth of the float is usually about  $\frac{1}{4}$  its length, and its thickness about  $\frac{1}{8}$  its breadth. The number of floats varies directly with the diameter, and there should be one float for every foot of diameter.

(For a discussion of the action of the radial wheel, see Thurston, Manual of the Steam-engine, part ii., p. 182.)

**Feathering Paddle-wheels.** (Seaton.)—The diameter of a feathering-wheel is found as follows: The amount of slip varies from 12 to 20 per cent, although when the floats are small or the resistance great it

is as high as 25 per cent; a well-designed wheel on a well-formed ship should not exceed 15 per cent under ordinary circumstances.

If  $K$  is the speed of the ship in knots,  $S$  the percentage of slip, and  $R$  the revolutions per minute,

$$\text{Diameter of wheel at centres} = \frac{K(100 + S)}{3.14 \times R}.$$

The diameter, however, must be such as will suit the structure of the ship, so that a modification may be necessary on this account, and the revolutions altered to suit it.

The diameter will also depend on the amount of "dip" or immersion of float.

When a ship is working always in smooth water the immersion of the top edge should not exceed  $\frac{1}{8}$  the breadth of the float; and for general service at sea an immersion of  $\frac{1}{2}$  the breadth of the float is sufficient. If the ship is intended to carry cargo, the immersion when light need not be more than 2 or 3 inches, and should not be more than the breadth of float when at the deepest draught; indeed, the efficiency of the wheel falls off rapidly with the immersion of the wheel.

$$\text{Area of one float} = \frac{\text{I.H.P.}}{D} \times C.$$

$C$  is a multiplier, varying from 0.3 to 0.35;  $D$  is the diameter of the wheel to the float centres, in feet.

$$\text{The number of floats} = \frac{1}{2}(D + 2).$$

$$\text{The breadth of the float} = 0.35 \times \text{the length.}$$

$$\text{The thickness of floats} = \frac{1}{12} \text{ the breadth.}$$

$$\text{Diameter of gudgeons} = \text{thickness of float.}$$

Seaton and Rounthwaite's Pocket-book gives:

$$\text{Number of floats} = \frac{60}{\sqrt{R}},$$

where  $R$  is number of revolutions per minute.

$$\text{Area of one float (in square feet)} = \frac{\text{I.H.P.} \times 33000 \times K}{N \times (D \times R)^3},$$

where  $N$  = number of floats in one wheel.

For vessels plying always in smooth water  $K = 1200$ . For sea-going steamers  $K = 1400$ . For tugs and such craft as require to stop and start frequently in a tide-way  $K = 1600$ .

It will be quite accurate enough if the last four figures of the cube  $(D \times R)^3$  be taken as ciphers.

For illustrated description of the feathering paddle-wheel see Seaton's Marine Engineering, or Seaton and Rounthwaite's Pocket-book. The diameter of a feathering-wheel is about one half that of a radial wheel for equal efficiency. (Thurston.)

**Efficiency of Paddle-wheels.**—Computations by Prof. Thurston of the efficiency of propulsion by paddle-wheels give for light river steamers with ratio of velocity of the vessel,  $v$ , to velocity of the paddle float at centre of pressure,  $V$ , or  $\frac{v}{V} = \frac{3}{4}$ , with a dip =  $\frac{3}{20}$  radius of the wheel, and a slip of 25 per cent, an efficiency of .714; and for ocean steamers with the same slip and ratio of  $\frac{v}{V}$ , and a dip =  $\frac{1}{8}$  radius, an efficiency of .685.

### JET-PROPULSION.

Numerous experiments have been made in driving a vessel by the reaction of a jet of water pumped through an orifice in the stern, but they have all resulted in commercial failure. Two jet-propulsion steamers, the "Waterwitch," 1100 tons, and the "Squirt," a small torpedo-boat, were built by the British Government. The former was tried in 1867, and gave an efficiency of apparatus of only 18 per cent. The latter gave a speed of 12 knots, as against 17 knots attained by a sister-ship having a screw and equal steam-power. The mathematical theory of the efficiency of the jet was discussed by Rankine in *The Engineer*, Jan. 11, 1867, and he showed that the greater the quantity of water operated on by a jet-propeller, the greater

is the efficiency. In defiance both of the theory and of the results of earlier experiments, and also of the opinions of many naval engineers, more than \$200,000 were spent in 1888-90 in New York upon two experimental boats, the "Prima Vista," and the "Evolution," in which the jet was made of very small size, in the latter case only  $\frac{5}{8}$ -inch diameter, and with a pressure of 2500 lbs. per square inch. As had been predicted, the vessel was a total failure. (See article by the author in *Mechanics*, March, 1891.)

The theory of the jet-propeller is similar to that of the screw-propeller. If  $A$  = the area of the jet in square feet,  $V$  its velocity with reference to the orifice, in feet per second,  $v$  = the velocity of the ship in reference to the earth, then the thrust of the jet (see Screw-propeller, *ante*) is  $2AV(V - v)$ . The work done on the vessel is  $2AV(V - v)v$ , and the work wasted on the rearward projection of the jet is  $\frac{1}{2} \times 2AV(V - v)^2$ . The efficiency is

$$\frac{2AV(V - v)v}{2AV(V - v)v + AV(V - v)^2} = \frac{2v}{V + v}$$
 This expression equals unity when  $V = v$ , that is, when the velocity of the jet with reference to the earth, or  $V - v = 0$ ; but then the thrust of the propeller is also 0. The greater the value of  $V$  as compared with  $v$ , the less the efficiency. For  $V = 20v$ , as was proposed in the "Evolution," the efficiency of the jet would be less than 10 per cent, and this would be further reduced by the friction of the pumping mechanism and of the water in pipes.

The whole theory of propulsion may be summed up in Rankine's words: "That propeller is the best, other things being equal, which drives astern the largest body of water at the lowest velocity."

It is practically impossible to devise any system of hydraulic or jet propulsion which can compare favorably, under these conditions, with the screw or the paddle-wheel.

**Reaction of a Jet.**—If a jet of water issues horizontally from a vessel, the reaction on the side of the vessel opposite the orifice is equal to the weight of a column of water the section of which is the area of the orifice, and the height is twice the head.

The propelling force in jet-propulsion is the reaction of the stream issuing from the orifice, and it is the same whether the jet is discharged under water, in the open air, or against a solid wall. For proof, see account of trials by C. J. Everett, Jr., given by Prof. J. Burkitt Webb, *Trans. A. S. M. E.*, xii. 904.

## RECENT PRACTICE IN MARINE ENGINES.

(From a paper by A. Blechynden on Marine Engineering during the past Decade, *Proc. Inst. M. E.*, July, 1891.)

Since 1881 the three-stage-expansion engine has become the rule, and the boiler-pressure has been increased to 160 lbs. and even as high as 200 lbs. per square inch. Four-stage-expansion engines of various forms have also been adopted.

**Forced Draught** has become the rule in all vessels for naval service, and is comparatively common in both passenger and cargo vessels. By this means it is possible considerably to augment the power obtained from a given boiler; and so long as it is kept within certain limits it need result in no injury to the boiler, but when pushed too far the increase is sometimes purchased at considerable cost.

In regard to the economy of forced draught, an examination of the appended table (page 1018) will show that while the mean consumption of coal in those steamers working under natural draught is 1.573 lbs. per indicated horse-power per hour, it is only 1.336 lbs. in those fitted with forced draught. This is equivalent to an economy of 15%. Part of this economy, however, may be due to the other heat-saving appliances with which the latter steamers are fitted.

**Boilers.**—As a material for boilers, iron is now a thing of the past, though it seems probable that it will continue yet awhile to be the material for tubes. Steel plates can be procured at 13 $\frac{1}{2}$  square feet superficial area and 1 $\frac{1}{2}$  inches thick. For purely boiler work a punching-machine has become obsolete in marine-engine work.

The increased pressures of steam have also caused attention to be directed to the furnace, and have led to the adoption of various artifices in the shape of corrugated, ribbed, and spiral flues, with the object of giving increased strength against collapse without abnormally increasing the thickness of the plate. A thick furnace-plate is viewed by many engineers with great

suspicion; and the advisers of the Board of Trade have fixed the limit of thickness for furnace-plates at  $\frac{5}{8}$  inch; but whether this limitation will stand in the light of prolonged experience remains to be seen. It is a fact generally accepted that the conditions of the surfaces of a plate are far greater factors in its resistance to the transmission of heat than either the material or the thickness. With a plate free from lamination, thickness being a mere secondary element, it would appear that a furnace-plate might be increased from  $\frac{1}{2}$  inch to  $\frac{3}{4}$  inch thickness without increasing its resistance more than  $1\frac{1}{4}\%$ . So convinced have some engineers become of the soundness of this view that they have adopted flues  $\frac{3}{4}$  inch thick.

**Piston-valves.**—Since higher steam-pressures have become common, piston-valves have become the rule for the high-pressure cylinder, and are not unusual for the intermediate. When well designed they have the great advantage of being almost free from friction, so far as the valve itself is concerned. In the earlier piston-valves it was customary to fit spring rings, which were a frequent source of trouble and absorbed a large amount of power in friction; but in recent practice it has become usual to fit springless adjustable sleeves.

For low-pressure cylinders piston-valves are not in favor; if fitted with spring rings their friction is about as great as and occasionally greater than that of a well-balanced slide-valve; while if fitted with springless rings there is always some leakage, which is irrecoverable. But the large port-clearances inseparable from the use of piston-valves are most objectionable; and with triple engines this is especially so, because with the customary late cut-off it becomes difficult to compress sufficiently for insuring economy and smoothness of working when in "full gear," without some special device.

**Steam-pipes.**—The failures of copper steam-pipes on large vessels have drawn serious attention both to the material and the modes of construction of the pipes. As the brazed joint is liable to be imperfect, it is proposed to substitute solid drawn tubes, but as these are not made of large sizes two or more tubes may be needed to take the place of one brazed tube. Reinforcing the ordinary brazed tubes by serving them with steel or copper wire, or by hooping them at intervals with steel or iron bands, has been tried and found to answer perfectly.

**Auxiliary Supply of Fresh Water—Evaporators.**—To make up the losses of water due to escape of steam from safety-valves, leakage at glands, joints, etc., either a reserve supply of fresh water is carried in tanks, or the supplementary feed is distilled from sea-water by special apparatus provided for the purpose. In practice the distillation is effected by passing steam, say from the first receiver, through a nest of tubes inside a still or evaporator, of which the steam-space is connected either with the second receiver or with the condenser. The temperature of the steam inside the tubes being higher than that of the steam either in the second receiver or in the condenser, the result is that the water inside the still is evaporated, and passes with the rest of the steam into the condenser, where it is condensed and serves to make up the loss. This plan localizes the trouble of the deposit, and frees it from its dangerous character, because an evaporator cannot become overheated like a boiler, even though it be neglected until it salts up solid; and if the same precautions are taken in working the evaporator which used to be adopted with low-pressure boilers when they were fed with salt water, no serious trouble should result.

**Weir's Feed-water Heater.**—The principle of a method of heating feed-water introduced by Mr. James Weir and widely adopted in the marine service is founded on the fact that, if the feed-water as it is drawn from the hot-well be raised in temperature by the heat of a portion of steam introduced into it from one of the steam-receivers, the decrease of the coal necessary to generate steam from the water of the higher temperature bears a greater ratio to the coal required without feed-heating than the power which would be developed in the cylinder by that portion of steam would bear to the whole power developed when passing all the steam through all the cylinders. Suppose a triple-expansion engine were working under the following conditions without feed-heating: boiler-pressure 150 lbs.; I.H.P. in high-pressure cylinder 398, in intermediate and low-pressure cylinders together 790, total 1188. The temperature of hot-well 100° F. Then with feed-heating the same engine might work as follows: the feed might be heated to 220° F., and the percentage of steam from the first receiver required to heat it would be 10.9%; the I.H.P. in the h.p. cylinder would be as before 398, and in the three cylinders it would be 1103, or 93% of the power developed without

feed-heating. Meanwhile the heat to be added to each pound of the feed-water at 220° F. for converting it into steam would be 1005 units against 1125 units with feed at 100° F., equivalent to an expenditure of only 89.4% of the heat required without feed-heating. Hence the expenditure of heat in relation to power would be  $89.4 \div 93.0 = 96.4\%$ , equivalent to a heat economy of 3.6%. If the steam for heating can be taken from the low-pressure receiver, the economy is about doubled.

**CONSTRUCTION OF BUILDINGS.\***

(Extract from the Building Laws of the City of New York, 1893.)

**Walls of Warehouses, Stores, Factories, and Stables.—**

25 feet or less in width between walls, not less than 12 in. to height of 40 ft.;  
 If 40 to 60 ft. in height, not less than 16 in. to 40 ft., and 12 in. thence to top;  
 60 to 80 " " " " " 20 " 25 " 16 " "  
 75 to 85 " " " " " 24 " 20 ft.; 20 in. to 60 ft., and 16 in. to top;

85 to 100 ft. in height, not less than 28 in. to 25 ft.; 24 in. to 50 ft.; 20 in. to 75 ft., and 16 in. to top;

Over 100 ft. in height, each additional 25 ft. in height, or part thereof, next above the curb, shall be increased 4 inches in thickness, the upper 100 feet remaining the same as specified for a wall of that weight.

If walls are over 25 feet apart, the bearing-walls shall be 4 inches thicker than above specified for every 12½ feet or fraction thereof that said walls are more than 25 feet apart.

**Strength of Floors, Roofs, and Supports.**

Floors calculated to bear safely per sq. ft., in addition to their own weight.

Floors of dwelling, tenement, apartment-house or hotel, not less than.....	70 lbs.
Floors of office-building, not less than....	100 "
" public-assembly building, not less than.....	120 "
" store, factory, warehouse, etc., not less than... ..	150 "
Roofs of all buildings, not less than.....	50 "

Every floor shall be of sufficient strength to bear safely the weight to be imposed thereon, in addition to the weight of the materials of which the floor is composed.

**Columns and Posts.**—The strength of all columns and posts shall be computed according to Gordon's formulæ, and the crushing weights in pounds, to the square incl of section, for the following-named materials, shall be taken as the coefficients in said formulæ, namely: Cast iron, 80,000;

\* The limitations of space forbid any extended treatment of this subject. Much valuable information upon it will be found in Trautwine's Civil Engineer's Pocket-book, and in Kidder's Architect's and Builder's Pocket-book. The latter in its preface mentions the following works of reference: "Notes on Building Construction," 3 vols., Rivingtons, publishers, Boston; "Building Superintendence," by T. M. Clark (J. R. Osgood & Co., Boston.); "The American House Carpenter," by R. G. Hatfield; "Graphical Analysis of Roof-trusses," by Prof. C. E. Greene; "The Fire Protection of Mills," by C. J. H. Woodbury; "House Drainage and Water Service," by James C. Bayles; "The Builder's Guide and Estimator's Price-book," and "Plastering Mortars and Cements," by Fred. T. Hodgson; "Foundations and Concrete Works," and "Art of Building," by E. Dobson, Weale's Series, London. J. H. Woodbury; "House Drainage and Water Service," by James C. Bayles; "The Builder's Guide and Estimator's Price-book," and "Plastering Mortars and Cements," by Fred. T. Hodgson; "Foundations and Concrete Works." and "Art of Building," by E. Dobson, Weale's Series, London.

wrought or rolled iron, 40,000; rolled steel, 48,000; white pine and spruce, 8500; pitch or Georgia pine, 5000; American oak, 6000. The breaking strength of wooden beams and girders shall be computed according to the formulæ in which the constants for transverse strains for central load shall be as follows, namely: Hemlock, 400; white pine, 450; spruce, 450; pitch or Georgia pine, 550; American oak, 550; and for wooden beams and girders carrying a uniformly distributed load the constants will be doubled. The factors of safety shall be as one to four for all beams, girders, and other pieces subject to a transverse strain; as one to four for all posts, columns, and other vertical supports when of wrought iron or rolled steel; as one to five for other materials, subject to a compressive strain; as one to six for tie-rods, tie-beams, and other pieces subject to a tensile strain. Good, solid, natural earth shall be deemed to safely sustain a load of four tons to the superficial foot, or as otherwise determined by the superintendent of buildings, and the width of footing-courses shall be at least sufficient to meet this requirement. In computing the width of walls, a cubic foot of brickwork shall be deemed to weigh 115 lbs. Sandstone, white marble, granite, and other kinds of building-stone shall be deemed to weigh 160 lbs. per cubic foot. The safe-bearing load to apply to good brickwork shall be taken at 8 tons per superficial foot when good lime mortar is used,  $11\frac{1}{2}$  tons per superficial foot when good lime and cement mortar mixed is used, and 15 tons per superficial foot when good cement mortar is used.

**Fire-proof Buildings—Iron and Steel Columns.**—All cast-iron, wrought-iron, or rolled-steel columns shall be made true and smooth at both ends, and shall rest on iron or steel bed-plates, and have iron or steel cap-plates, which shall also be made true. All iron or steel trimmer-beams, headers, and tail-beams shall be suitably framed and connected together, and the iron girders, columns, beams, trusses, and all other ironwork of all floors and roofs shall be strapped, bolted, anchored, and connected together, and to the walls, in a strong and substantial manner. Where beams are framed into headers, the angle irons, which are bolted to the tail-beams, shall have at least two bolts for all beams over 7 inches in depth, and three bolts for all beams 12 inches and over in depth, and these bolts shall not be less than  $\frac{3}{4}$  inch in diameter. Each one of such angles or knees, when bolted to girders, shall have the same number of bolts as stated for the other leg. The angle-iron in no case shall be less in thickness than the header or trimmer to which it is bolted, and the width of angle in no case shall be less than one third the depth of beam, excepting that no angle-knee shall be less than  $2\frac{1}{2}$  inches wide, nor required to be more than 6 inches wide. All wrought-iron or rolled-steel beams 8 inches deep and under shall have bearings equal to their depth, if resting on a wall; 9 to 12 inch beams shall have a bearing of 10 inches, and all beams more than 12 inches in depth shall have bearings of not less than 12 inches if resting on a wall. Where beams rest on iron supports, and are properly tied to the same, no greater bearings shall be required than one third of the depth of the beams. Iron or steel floor-beams shall be so arranged as to spacing and length of beams that the load to be supported by them, together with the weights of the materials used in the construction of the said floors, shall not cause a deflection of the said beams of more than  $\frac{1}{30}$  of an inch per linear foot of span; and they shall be tied together at intervals of not more than eight times the depth of the beam.

Under the ends of all iron or steel beams, where they rest on the walls, a stone or cast-iron template shall be built into the walls. Said template shall be 8 inches wide in 12-inch walls, and in all walls of greater thickness said template shall be 12 inches wide; and such templates, if of stone, shall not be in any case less than  $2\frac{1}{2}$  inches in thickness, and no template shall be less than 12 inches long.

No cast iron post or column shall be used in any building of a less average thickness of shaft than three quarters of an inch, nor shall it have an unsupported length of more than twenty times its least lateral dimensions or diameter. No wrought-iron or rolled-steel column shall have an unsupported length of more than thirty times its least lateral dimension or diameter, nor shall its metal be less than one fourth of an inch in thickness.

**Lintels, Bearings and Supports.**—All iron or steel lintels shall have bearings proportionate to the weight to be imposed thereon, but no lintel used to span any opening more than 10 feet in width shall have a bearing less than 12 inches at each end, if resting on a wall; but if resting on an iron post, such lintel shall have a bearing of at least 6 inches at each end, by the thickness of the wall to be supported.

**Strains on Girders and Rivets.**—Rolled iron or steel beam gir-

ders, or riveted iron or steel plate girders used as lintels or as girders, carrying a wall or floor or both, shall be so proportioned that the loads which may come upon them shall not produce strains in tension or compression upon the flanges of more than 12,000 lbs. for iron, nor more than 15,000 lbs. for steel per square inch of the gross section of each of such flanges, nor a shearing strain upon the web-plate of more than 6000 lbs. per square inch of section of such web-plate, if of iron, nor more than 7000 pounds if of steel; but no web-plate shall be less than  $\frac{1}{4}$  inch in thickness. Rivets in plate girders shall not be less than  $\frac{5}{8}$  inch in diameter, and shall not be spaced more than 6 inches apart in any case. They shall be so spaced that their shearing strains shall not exceed 9000 lbs. per square inch, on their diameter, multiplied by the thickness of the plates through which they pass. The riveted plate girders shall be proportioned upon the supposition that the bending or chord strains are resisted entirely by the upper and lower flanges, and that the shearing strains are resisted entirely by the web-plate. No part of the web shall be estimated as flange area, nor more than one half of that portion of the angle-iron which lies against the web. The distance between the centres of gravity of the flange areas will be considered as the effective depth of the girder.

The building laws of the City of New York contain a great amount of detail in addition to the extracts above, and penalties are provided for violation. See An Act creating a Department of Buildings, etc., Chapter 275, Laws of 1892. Pamphlet copy published by Baker, Voorhies & Co., New York.

**MAXIMUM LOAD ON FLOORS.**

(*Eng'g*, Nov. 18, 1892. p. 644.)—Maximum load per square foot of floor surface due to the weight of a dense crowd. Considerable variation is apparent in the figures given by many authorities, as the following table shows:

Authorities.	Weight of Crowd, lbs. per sq. ft.
French practice, quoted by Trautwine and Stoney .....	41
Hatfield ("Transverse Strains," p. 80) .....	70
Mr. Page, London, quoted by Trautwine.....	84
Maximum load on American highway bridges according to Waddell's general specifications... ..	100
Mr. Nash, architect of Buckingham Palace.....	120
Experiments by Prof. W. N. Kernot, at Melbourne .....	126
Experiments by Mr. B. B. Stoney ("On Stresses," p. 617) ...	143.1
	147.4

The highest results were obtained by crowding a number of persons previously weighed into a small room, the men being tightly packed so as to resemble such a crowd as frequently occurs on the stairways and platforms of a theatre or other public building.

**STRENGTH OF FLOORS.**

(From circular of the Boston Manufacturers' Mutual Insurance Co.)

The following tables were prepared by C. J. H. Woodbury, for determining safe loads on floors. Care should be observed to select the figure giving the greatest possible amount and concentration of load as the one which may be put upon any beam or set of floor-beams; and in no case should beams be subjected to greater loads than those specified, unless a lower factor of safety is warranted under the advice of a competent engineer.

Whenever and wherever solid beams or heavy timbers are made use of in the construction of a factory or warehouse, they should not be painted, varnished or oiled, filled or encased in impervious concrete, air-proof plastering, or metal for at least three years, lest fermentation should destroy them by what is called "dry rot."

It is, on the whole, safer to make floor-beams in two parts, with a small open space between, so that proper ventilation may be secured, even if the outside should be inadvertently painted or filled.

These tables apply to distributed loads, but the first can be used in respect to floors which may carry concentrated loads by using half the figure given in the table, since a beam will bear twice as much load when evenly distributed over its length as it would if the load was concentrated in the centre of the span.

The weight of the floor should be deducted from the figure given in the table, in order to ascertain the net load which may be placed upon any floor. The weight of spruce may be taken at 36 lbs. per cubic foot, and that of Southern pine at 48 lbs. per cubic foot.

Table I was computed upon a working modulus of rupture of Southern pine at 2160 lbs., using a factor of safety of six. It can also be applied to ascertaining the strength of spruce beams if the figures given in the table are multiplied by 0.78; or in designing a floor to be sustained by spruce beams, multiply the required load by 1.28, and use the dimensions as given by the table.

These tables are computed for beams one inch in width, because the strength of beams increases directly as the width when the beams are broad enough not to cripple.

EXAMPLE.—Required the safe load per square foot of floor, which may be safely sustained by a floor on Southern pine 10 × 14 inch beams, 8 feet on centres, and 20 feet span. In Table I a 1 × 14 inch beam, 20 feet span, will sustain 118 lbs. per foot of span; and for a beam 10 inches wide the load would be 1180 lbs. per foot of span, or 147½ lbs. per square foot of floor for Southern-pine beams. From this should be deducted the weight of the floor, which would amount to 17½ lbs. per square foot, leaving 130 lbs. per square foot as a safe load to be carried upon such a floor. If the beams are of spruce, the result of 147½ lbs. would be multiplied by 0.78, reducing the load to 115 lbs. The weight of the floor, in this instance amounting to 16 lbs., would leave the safe net load as 90 lbs. per square foot for spruce beams.

Table II applies to the design of floors whose strength must be in excess of that necessary to sustain the weight, in order to meet the conditions of delicate or rapidly moving machinery, to the end that the vibration or distortion of the floor may be reduced to the least practicable limit.

In the table the limit is that of load which would cause a bending of the beams to a curve of which the average radius would be 1250 feet.

This table is based upon a modulus of elasticity obtained from observations upon the deflection of loaded storehouse floors, and is taken at 2,000,000 lbs. for Southern pine; the same table can be applied to spruce, whose modulus of elasticity is taken as 1,200,000 lbs., if six tenths of the load for Southern pine is taken as the proper load for spruce; or, in the matter of designing, the load should be increased one and two thirds times, and the dimension of timbers for this increased load as found in the table should be used for spruce.

It can also be applied to beams and floor-timbers which are supported at each end and in the middle, remembering that the deflection of a beam supported in that manner is only four tenths that of a beam of equal span which rests at each end; that is to say, the floor-planks are two and one half times as stiff, cut two bays in length, as they would be if cut only one bay in length. When a floor-plank two bays in length is evenly loaded, three sixteenths of the load on the plank is sustained by the beam at each end of the plank, and ten sixteenths by the beam under the middle of the plank; so that for a completed floor three eighths of the load would be sustained by the beams under the joints of the plank, and five eighths of the load by the beams under the middle of the plank: this is the reason of the importance of breaking joints in a floor-plank every three feet in order that each beam shall receive an identical load. If it were not so, three eighths of the whole load upon the floor would be sustained by every other beam, and five eighths of the load by the corresponding alternate beams.

Repeating the former example for the load on a mill floor on Southern-pine beams 10 × 14 inches, and 20 feet span, laid 8 feet on centres: In Table II a 1 × 14 inch beam should receive 61 lbs. per foot of span, or 75 lbs. per sq. ft. of floor, for Southern-pine beams. Deducting the weight of the floor, 17½ lbs. per sq. ft., leaves 57 lbs. per sq. ft. as the advisable load.

If the beams are of spruce, the result of 75 lbs. should be multiplied by 0.6, reducing the load to 45 lbs. The weight of the floor, in this instance amounting to 16 lbs., would leave the net load as 29 lbs. for spruce beams.

If the beams were two spans in length, they could, under these conditions, support two and a half times as much load with an equal amount of deflection, unless such load should exceed the limit of safe load as found by Table I, as would be the case under the conditions of this problem.

**Mill Columns.**—Timber posts offer more resistance to fire than iron pillars, and have generally displaced them in millwork. Experiments made on the testing-machine at the U. S. Arsenal at Watertown, Mass., show that sound timber posts of the proportions customarily used in millwork yield by direct crushing, the strength being directly as the area at the smallest part. The columns yielded at about 4500 lbs. per square inch, confirming the general practice of allowing 600 lbs. per square inch, as a safe load. Square columns are one fourth stronger than round ones of the same diameter.

**I. Safe Distributed Loads upon Southern-pine Beams One Inch in Width.**

(C. J. H. Woodbury.)

(If the load is concentrated at the centre of the span, the beams will sustain half the amount as given in the table.)

## ELECTRICAL ENGINEERING.

## STANDARDS OF MEASUREMENT.

**C.G.S. (Centimetre, Gramme, Second) or "Absolute" System of Physical Measurements:**

Unit of space or distance	= 1 centimetre, cm.;
Unit of mass	= 1 gramme, gm.;
Unit of time	= 1 second, s.;
Unit of velocity = space ÷ time	= 1 centimetre in 1 second;
Unit of acceleration = change of 1 unit of velocity in 1 second;	
Acceleration due to gravity, at Paris,	= 981 centimetres in 1 second;
Unit of force = 1 dyne = $\frac{1}{981}$ gramme	= $\frac{.0022046}{981}$ lb. = .000002247 lb.

A dyne is that force which, acting on a mass of one gramme during one second, will give it a velocity of one centimetre per second. The weight of one gramme in latitude 40° to 45° is about 980 dynes, at the equator 973 dynes, and at the poles nearly 984 dynes. Taking the value of  $g$ , the acceleration due to gravity, in British measures at 32.185 feet per second at Paris, and the metre = 39.37 inches, we have

$$1 \text{ gramme} = 32.185 \times 12 \div .3937 = 981.00 \text{ dynes.}$$

Unit of work = 1 erg	= 1 dyne-centimetre = .00000007373 foot-pound ;
Unit of power = 1 watt	= 10 million ergs per second,
	= .7373 foot-pound per second,
	= $\frac{.7373}{550} = \frac{1}{746}$ of 1 horse-power = .00134 H.P.

C.G.S. Unit of magnetism = the quantity which attracts or repels an equal quantity at a centimetre's distance with the force of 1 dyne.

C.G.S. Unit of electrical current = the current which, flowing through a length of 1 centimetre of wire, acts with a force of 1 dyne upon a unit of magnetism distant 1 centimetre from every point of the wire. The ampere, the commercial unit of current, is one tenth of the C.G.S. unit.

**The Practical Units used in Electrical Calculations are:**

*Ampere*, the unit of current strength, or rate of flow, represented by  $I$ .

*Volt*, the unit of electro-motive force, electrical pressure, or difference of potential, represented by  $E$ .

*Ohm*, the unit of resistance, represented by  $R$ .

*Coulomb* (or ampere-second), the unit of quantity,  $Q$ .

*Ampere-hour* = 3600 coulombs,  $Q'$ .

*Watt* (ampere-volt, or volt-ampere), the unit of power,  $P$ .

*Joule* (volt-coulomb), the unit of energy or work,  $W$ .

*Farad*, the unit of capacity, represented by  $C$ .

*Henry*, the unit of inductance, represented by  $L$ .

Using letters to represent the units, the relations between them may be expressed by the following formulæ, in which  $t$  represents one second and  $T$  one hour:

$$I = \frac{E}{R}, \quad Q = It, \quad Q' = IT, \quad C = \frac{Q}{E}, \quad W = QE, \quad P = IE.$$

As these relations contain no coefficient other than unity, the letters may represent any quantities given in terms of those units. For example, if  $E$  represents the number of volts electro-motive force, and  $R$  the number of ohms resistance in a circuit, then their ratio  $E \div R$  will give the number of amperes current strength in that circuit.

The above six formulæ can be combined by substitution or elimination, so as to give the relations between any of the quantities. The most important of these are the following :

$$Q = \frac{E}{R}t, \quad C = \frac{I}{E}t, \quad W = IEt = \frac{E^2}{R}t = I^2Rt = Pt,$$

$$E = IR, \quad R = \frac{E}{I}, \quad P = \frac{E^2}{R} = I^2R = \frac{W}{t} = \frac{QE}{t}.$$

The definitions of these units as adopted at the International Electrical Congress at Chicago in 1893, and as established by Act of Congress of the United States, July 12, 1894, are as follows:

The *ohm* is substantially equal to  $10^9$  (or 1,000,000,000) units of resistance of the C.G.S. system, and is represented by the resistance offered to an unvarying electric current by a column of mercury at  $32^\circ$  F., 14.4521 grammes in mass, of a constant cross-sectional area, and of the length of 106.3 centimetres.

The *ampere* is  $1/10$  of the unit of current of the C.G.S. system, and is the practical equivalent of the unvarying current which when passed through a solution of nitrate of silver in water in accordance with standard specifications deposits silver at the rate of .001118 gramme per second.

The *volt* is the electro-motive force that, steadily applied to a conductor whose resistance is one ohm, will produce a current of one ampere, and is practically equivalent to  $1000/1434$  (or .6974) of the electro-motive force between the poles or electrodes of a Clark's cell at a temperature of  $15^\circ$  C., and prepared in the manner described in the standard specifications.

The *coulomb* is the quantity of electricity transferred by a current of one ampere in one second.

The *farad* is the capacity of a condenser charged to a potential of one volt by one coulomb of electricity.

The *joule* is equal to 10,000,000 units of work in the C.G.S. system, and is practically equivalent to the energy expended in one second by an ampere in an ohm.

The *watt* is equal to 10,000,000 units of power in the C.G.S. system, and is practically equivalent to the work done at the rate of one joule per second.

The *henry* is the induction in a circuit when the electro-motive force induced in this circuit is one volt, while the inducing current varies at the rate of one ampere per second.

The ohm, volt, etc., as above defined, are called the "international" ohm, volt, etc., to distinguish them from the "legal" ohm, B.A. unit, etc.

The value of the ohm, determined by a committee of the British Association in 1863, called the B.A. unit, was the resistance of a certain piece of copper wire. The so-called "legal" ohm, as adopted at the International Congress of Electricians in Paris in 1884, was a correction of the B.A. unit, and was defined as the resistance of a column of mercury 1 square millimetre in section and 106 centimetres long, at a temperature of  $32^\circ$  F.

1 legal ohm	= 1.0112 B.A. units,	1 B.A. unit	= 0.9889 legal ohm;
1 international ohm	= 1.0136 " " "	1 " " "	= 0.9866 int. ohm;
1 " " "	= 1.0023 legal ohm,	1 legal ohm	= 0.9977 " " "

#### DERIVED UNITS.

1 megohm	= 1 million ohms;
1 microhm	= 1 millionth of an ohm;
1 milliamper	= $1/1000$ of an ampere;
1 micro-farad	= 1 millionth of a farad.

#### RELATIONS OF VARIOUS UNITS.

1 ampere.....	= 1 coulomb per second;		
1 volt-ampere.....	= 1 watt = 1 volt-coulomb per second;		
1 watt.....	} = .7373 foot-pound per second, = .0009477 heat-units per second (Fahr.), = $1/746$ of one horse-power;		
		1 joule.....	} = .7373 foot-pound, = work done by one watt in one second, = .0009477 heat-unit;
1 kilowatt, or 1000 watts.....	= $1000/746$ or 1.3405 horse-powers;		
1 kilowatt-hour,	} = 1.3405 horse-power hours, = 2,654,200 foot-pounds, = 3412 heat-units;		
1000 volt-ampere hours,			
1 British Board of Trade unit,			
1 horse-power.....	} = 746 watts = 746 volt-amperes, = 33,000 foot-pounds per minute.		

The ohm, ampere, and volt are defined in terms of one another as follows: Ohm, the resistance of a conductor through which a current of one ampere will pass when the electro-motive force is one volt. Ampere, the quantity of current which will flow through a resistance of one ohm when the electro-motive force is one volt. Volt, the electro-motive force required to cause a current of one ampere to flow through a resistance of one ohm.

## Equivalent Values of Electrical and Mechanical Units.

**Units of the Magnetic Circuit.**—(See Electro-magnets, page 1052.)  
**For Methods of making Electrical Measurements, Testing, etc.,** see Munroe & Jamieson's Pocket-Book of Electrical Rules, Tables, and Data; S. P. Thompson's Dynamo-Electric Machinery; Carhart & Patterson's Electrical Measurements; and works on Electrical Engineering.

**Equivalent Electrical and Mechanical Units.**—H. Ward Leonard published in *The Electrical Engineer*, Feb. 25, 1895, a table of useful equivalents of electrical and mechanical units, from which the table on page 1026 is taken, with some modifications.

**ANALOGIES BETWEEN THE FLOW OF WATER AND ELECTRICITY.**

**WATER.**

**ELECTRICITY.**

Head, difference of level, in feet.	}	Volts; electro-motive force; difference of potential; E. or E.M.F.
Difference of pressure, lbs. per sq. in.		Ohms, resistance, $R$ . Increases directly as the length of the conductor or wire and inversely as its sectional area, $R \propto l \div s$ . It varies with the nature of the conductor.
Resistance of pipes, apertures, etc., increases with length of pipe, with contractions, roughness, etc.; decreases with increase of sectional area.	}	Amperes; current; current strength; intensity of current; rate of flow; 1 ampere = 1 coulomb per second.
Rate of flow, as cubic ft. per second, gallons per minute, etc., or volume divided by the time. In the mining regions sometimes expressed in "miners' inches."		Amperes = $\frac{\text{volts}}{\text{ohms}}$ ; $I = \frac{E}{R}$ ; $E = IR$ .
Quantity, usually measured in cubic ft. or gallons, but is also equivalent to rate of flow $\times$ time, as cu. ft. per second for so many hours.	}	Coulomb, unit of quantity, $Q$ , = rate of flow $\times$ time, as ampere-seconds. 1 ampere-hour = 3600 coulombs.
Work, or energy, measured in foot-pounds; product of weight of falling water into height of fall; in pumping, product of quantity in cubic feet into the pressure in lbs. per square foot against which the water is pumped.		Joule, volt-coulomb, $W$ , the unit of work, = product of quantity by the electro-motive force = volt-ampere-second. 1 joule = .7373 foot-pound. If $C$ (amperes) = rate of flow, and $E$ (volts) = difference of pressure between two points in a circuit, energy expended = $IEt$ , = $I^2Rt$ .
Power, rate of work. Horse-power = ft.-lbs. of work in 1 min. $\div$ 33,000. In water flowing in pipes, rate of flow in cu. ft. per second $\times$ resistance to the flow in lbs. per sq. ft. $\div$ 550.	}	Watt, unit of power, $P$ , = volts $\times$ amperes, = current or rate of flow $\times$ difference of potential. 1 watt = .7373 foot-pound per second = 1/746 of a horse-power.

**ELECTRICAL RESISTANCE.**

**Laws of Electrical Resistance.**—The resistance,  $R$ , of any conductor varies directly as its length,  $l$ , and inversely as its sectional area,  $s$ , or  $R \propto l \div s$ .

If  $r$  = the resistance of a conductor 1 unit in length and 1 square unit in sectional area,  $R = rl \div s$ . The common unit of length for electrical calculations in English measure is the foot, and the unit of area of wires is the circular mil = the area of a circle 0.001 in. diameter. 1 mil-foot = 1 foot long 1 circ.-mil area.

Resistance of 1 mil-foot of soft copper wire at 51° F. = 10 international ohms.

**EXAMPLE.**—What is the resistance of a wire 1000 ft. long, 0.1 in. diam.? 0.1 in. diam. = 10,000 circ. mils.

$$R = rl \div s = 10 \times 1000 \div 10,000 = 1 \text{ ohm.}$$

Specific resistance, also called resistivity, is the resistance of a material of unit length and section as compared with the resistance of soft copper.

Conductivity is the reciprocal of specific resistance, or the relative conducting power compared with copper taken at 100.

**Relative Conductivities of Different Metals at 0° and 100° C. (Matthiessen.)**

Metals.	Conductivities.		Metals.	Conductivities.

**Electrical Conductivity of Different Metals and Alloys.**

The following figures of electrical conductivity are given by Lazare Weiler

Pure silver.....	100	Swedish iron.....	16
Pure copper.....	100	Pure Banca tin.....	15.45
Telegraphic silicious bronze..	98	Aluminum bronze (10%).....	12.6
Alloy of ½ copper, ½ silver..	86.65	Siemens steel.....	12
Pure gold.....	78	Pure platinum....	10.6
Silicide of copper, 4% Si.....	75	Copper with 10% of nickel.....	10.6
Telephonic silicious bronze...	35	Pure lead.....	8.88
Pure zinc.....	29.9	Bronze with 20% of tin.....	8.4
Brass with 35% of zinc.....	21.5	Pure nickel.....	7.89
Phosphor tin.....	17.7	Phosphor-bronze, 10% tin....	6.5
Alloy of ½ gold, ½ silver....	16.13	Antimony.....	3.88

**Conductivity of Aluminum.**—J. W. Richards (*Jour. Frank. Inst.*, Mar. 1897) gives for hard-drawn aluminum of purity 98.5, 99.0, 99.5, and 99.75% respectively a conductivity of 55, 59, 61, and 63 to 64%, copper being 100%. The Pittsburg Reduction Co. claims that its purest aluminum has a conductivity of over 64.5%. (*Eng'g News*, Dec. 17, 1896.)

**German Silver.**—The resistance of German silver depends on its composition. Matthiessen gives it as nearly 13 times that of copper, with a temperature coefficient of .0004433 per degree C. Weston, however (*Proc. Electrical Congress 1893*, p. 179), has found copper-nickel-zinc alloys (German silver) which had a resistance of nearly 28 times that of copper, and a temperature coefficient of about one half that given by Matthiessen.

**Conductors and Insulators in Order of their Value.**

CONDUCTORS.	INSULATORS (NON-CONDUCTORS).
All metals	Dry air
Well-burned charcoal	Shellac
Plumbago	Paraffin
Acid solutions	Amber
Saline solutions	Resins
Metallic ores	Sulphur
Animal fluids	Wax
Living vegetable substances	Jet
Moist earth	Glass
Water	Mica
	Ebonite
	Gutta-percha
	India-rubber
	Silk
	Dry paper
	Parchment
	Dry leather
	Porcelain
	Oils

According to Culley, the resistance of distilled water is 6754 million times as great as that of copper. Impurities in water decrease its resistance.

**Resistance Varies with Temperature.**—For every degree Centigrade the resistance of copper increases about 0.4% or for every degree F. 0.2222%. Thus a piece of copper wire having a resistance of 10 ohms at 32° would have a resistance of 11.11 ohms at 82° F.

The following table shows the amount of resistance of a few substances used for various electrical purposes by which 1 ohm is increased by a rise of temperature of 1° C.

Platinum.....	.00031	Gold, silver.....	.00065
Platinum silver.....	.00031	Cast iron.....	.00080
German silver (see above).....	.00044	Copper.....	.00400

**Annealing.**—Resistance is lessened by annealing. Matthiessen gives the following relative conductivities for copper and silver, the comparison being made with pure silver at 100° C.:

Metal.	Temp. C.	Hard.	Annealed.	Ratio.
Copper.....	11°	95.31	97.83	1 to 1.027
Silver.....	14.6°	95.36	103.33	1 to 1.084

Dr. Siemens compared the conductivities of copper, silver, and brass with the following results. Ratio of hard to annealed:

Copper.....	1 to 1.058	Silver.....	1 to 1.145	Brass... ..	1 to 1.180
-------------	------------	-------------	------------	-------------	------------

**Standard of Resistance of Copper Wire.** (Trans. A. I. E. E., Sept. and Nov. 1893).—Matthiessen's standard is: A hard-drawn copper wire 1 metre long, weighing 1 gramme, has a resistance of 0.1469 B.A. unit at 0° C. Relative conducting power (Matthiessen): silver, 100; hard or unannealed copper, 99.95; soft or annealed copper, 102.21. Conductivity of copper at other temperatures than 0° C.,  $C_t = C_0(1 - .00387t + .00009009t^2)$ .

The resistance is the reciprocal of the conductivity, and is

$$R_t = R_0(1 + .00387t + .0000597t^2).$$

The shorter formula  $R_t = R_0(1 + .00406t)$  is commonly used.

A committee of the Am. Inst. Electrical Engineers recommend the following as the most correct form of the Matthiessen standard, taking 8.89 as the sp. gr. of pure copper:

A soft copper wire 1 metre long and 1 mm. diam. has an electrical resistance of .02057 B.A. unit at 0° C. From this the resistance of a soft copper wire 1 foot long and .001 in. diam. (mil-foot) is 9.720 B.A. units at 0° C.

Standard Resistance at 0° C.	B.A. Units.	Legal Ohms.	Internat. Ohms.
Max 2-millimetre, soft copper.....	.02057	.02034	.02029
Cubic centimetre " ".....	.000001616	.000001598	.000001593
Mil-foot " ".....	9.720	9.612	9.590
1 mil-foot. of soft copper at 10° 22 C. or 50° 4 F... ..		10	9.977
" " " " " " 15° 5 " 59° 9 F... ..		10.20	10.175
" " " " " " 23° 9 " 75° F... ..		10.53	10.505

For tables of the resistance of copper wire, see pages 218 to 220, also pp. 1034, 1035.

Taking Matthiessen's standard of pure copper as 100%, some refined metal has exhibited an electrical conductivity equivalent to 103%.

Matthiessen found that impurities in copper sufficient to decrease its density from 8.94 to 8.90 produced a marked increase of electrical resistance.

**DIRECT ELECTRIC CURRENTS.**

**Ohm's Law.**—This law expresses the relation between the three fundamental units of resistance, electrical pressure, and current. It is:

$$\text{Current} = \frac{\text{electrical pressure}}{\text{resistance}}; I = \frac{E}{R}; \text{whence } E = IR, \text{ and } R = \frac{E}{I}.$$

In terms of the units of the three quantities,

$$\text{Amperes} = \frac{\text{volts}}{\text{ohms}}; \text{volts} = \text{amperes} \times \text{ohms}; \text{ohms} = \frac{\text{volts}}{\text{amperes}}.$$

**EXAMPLES: Simple Circuits.**—1. If the source has an effective electrical pressure of 100 volts, and the resistance is two ohms, what is the current?

$$I = \frac{E}{R} = \frac{100}{2} = 50 \text{ amperes.}$$

2. What pressure will give a current of 50 amperes through a resistance of 2 ohms?  $E = IR = 50 \times 2 = 100$  volts.

3. What resistance is required to obtain a current of 50 amperes when the pressure is 100 volts?  $R = E \div I = 100 \div 50 = 2$  ohms.

Ohm's law applies equally to a complete electrical circuit and to any part thereof.

**Series Circuits.**—If conductors are arranged one after the other they

are said to be in series, and the total resistance of the circuit is the sum of the resistances of its several parts. Let *A*, Fig. 170, be a source of current, such as a battery or generator, producing a difference of potential or E. M. F. of 120 volts, measured across *ab*, and let the circuit contain four conductors whose resistances,  $r_1, r_2, r_3, r_4$ , are 1 ohm each, and three other resistances,  $R_1, R_2, R_3$ , each 2 ohms. The total resistance is 10 ohms, and by Ohm's law the current  $I = E \div R = 120 \div 10 = 12$  amperes.

This current is constant throughout the circuit, and a series circuit is therefore one of *constant current*. The *drop of potential* in the whole circuit from *a* around to *b* is 120 volts, or  $E = RI$ . The drop in any portion depends on the resistance of that portion; thus from *a* to  $R_1$  the resistance is 1 ohm, the constant current 12 amperes, and the drop  $1 \times 12 = 12$  volts. The drop in passing through each of the resistances  $R_1, R_2, R_3$  is  $2 \times 12 = 24$  volts.

**Parallel, Divided, or Multiple Circuits.**—Let *B*, Fig. 171, be a generator producing an E. M. F. of 220 volts across the terminals *ab*. The current is divided, so that part flows through the main wires *ac* and part through the "shunt" *s*, having a resistance of 0.5 ohm. Also the current has three paths between *c* and *d*, viz., through the three resistances in parallel  $R_1, R_2, R_3$ , of 2 ohms each. Consider that the resistance of the wires is so small that it may be neglected. Let the conductances of the four paths be represented by  $C_s, C_1, C_2, C_3$ . The total conductance is  $C_s + C_1 + C_2 + C_3 = C$  and the total resistance  $R = 1 \div C$ . The conductance of each path is the reciprocal of its resistance, the total conductance is the sum of the separate conductances, and the resistance of the combined or "parallel" paths is the reciprocal of the total conductance.

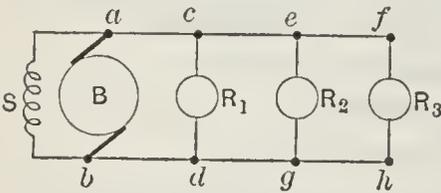

FIG. 171.

$+ C_2 + C_3 = C$  and the total resistance  $R = 1 \div C$ . The conductance of each path is the reciprocal of its resistance, the total conductance is the sum of the separate conductances, and the resistance of the combined or "parallel" paths is the reciprocal of the total conductance.

$$R = 1 \div \left( \frac{1}{0.5} + \frac{1}{2} + \frac{1}{2} + \frac{1}{2} \right) = 1 \div 3.5 = 0.286 \text{ ohm.}$$

The current  $I = E \div R = 770$  amperes.

**Conductors in Series and Parallel.**—Let the resistances in parallel be the same as in Fig. 171, with the additional resistance of 0.1 ohm in each of the six sections of the main wires, *ac, bd, etc.*, in series. The voltage across *ab* being 220 volts, determine the drop in voltage at the several points, the total current, and the current through each path. The problem is somewhat complicated. It may be solved as follows: Consider first the points *eg*; here there are two paths for the current, *efgh* and *eg*. Find the resistance and the conductance of each and the total resistance (the reciprocal of the joint conductance) of the parallel paths. Next consider the points *cd*; here there are two paths—one through *e* and the other through *cd*. Find the total resistance as before. Finally consider the points *ab*; here there are two paths—one through *c*, the other through *s*. Find the conductances of each and their sum. The product of this sum and the voltage at *ab* will be the total amperes of current, and the current through any path will be proportional to the conductance of that path. The resistances, *R*, and conductances, *C*, of the several paths are as follows:

$R_a$ of <i>efgh</i>	$= 0.1 + 2 + 0.1 = 2.2$	$C$	$0.4545$
$R_b$ of <i>eg</i>	$= 2$		$0.5$
	Joint $R_c = 1.048$		$0.9545$
$R_d$ of <i>ce + dg + Ro</i>	$= 1.248$		$0.8013$
$R_e$ of <i>cR1d</i>	$= 2$		$0.5$
	Joint $R_f = 0.7687$		$1.3013$
$R_g$ of <i>ac + bd + Rf</i>	$= 0.9687$		$1.0332$
$R_h$ of <i>s</i>	$= 0.5$		$2$
	Joint $R_g + R_h = 0.330$		$3.0332$

$$\begin{aligned} \text{Total current} &= 220 \times 3.0332 = 667.3 \text{ amperes.} \\ \text{Current through } s &= 220 \times 2 = 440 \text{ amp.}; \text{ through } c = 227.3 \text{ amp.} \\ \text{“ “ } cR_1d &= 227.3 \times 0.5 \div 1.3013 = 87.34 \text{ amp.} \\ \text{“ “ } e &= 227.3 \times 0.8013 \div 1.3013 = 139.96 \text{ “} \\ \text{“ “ } eR_2g &= 139.96 \times 0.5 \div 0.9545 = 73.31 \text{ “} \\ \text{“ “ } fR_3 &= 139.96 \times 0.4545 \div 0.9545 = 66.65 \text{ “} \end{aligned}$$

The drop in voltage in any section of the line is found by the formula  $E = RI$ ,  $R$  being the resistance of that section and  $I$  the current in it. As the  $R$  of each section is 0.1 ohm we find  $E$  for  $ac$  and  $bd$  each = 22.7 volts, for  $ce$  and  $dg$  each 14.0 volts, and for  $ef$  and  $gh$  each 6.67 volts. The voltage across  $cd$  is  $220 - 2 \times 22.7 = 174.6$  volts; across  $eg$ ,  $174.6 - 2 \times 14.0 = 146.6$ , and across  $fh$   $146.6 - 2 \times 66.7 = 133.3$  volts. Taking these voltages and the resistances  $R_1, R_2, R_3$ , each 2 ohms, we find from  $I = E \div R$  the current through each of these resistances 87.3, 73.3, and 66.65 amperes, as before.

**Internal Resistance.**—In a simple circuit we have two resistances, that of the circuit  $R$  and that of the internal parts of the source of electro-motive force, called internal resistance,  $r$ . The formula of Ohm's law when the internal resistance is considered is  $I = E \div (R + r)$ .

**Power of the Circuit.**—The power, or rate of work, in watts = current in amperes  $\times$  electro-motive force in volts =  $I \times E$ . Since  $I = E \div R$ , watts =  $E^2 \div R$  = electro-motive force<sup>2</sup>  $\div$  resistance.

**EXAMPLE.**—What H.P. is required to supply 100 lamps of 40 ohms resistance each, requiring an electro-motive force of 60 volts?

The number of volt-amperes for each lamp is  $\frac{E^2}{R} = \frac{60^2}{40}$ , 1 volt-ampere = .00134 H.P.; therefore  $\frac{60^2}{40} \times 100 \times .00134 = 12$  H.P. (electrical) very nearly.

**Electrical, Brake, and Indicated Horse-power.**—The power given out by a dynamo = volts  $\times$  amperes  $\div$  1000 = kilowatts, kw. Volts  $\times$  amperes  $\div$  746 = electrical horse-power, E.H.P. The power put into a dynamo shaft by a direct-connected engine or other prime mover is called the shaft or brake horse-power, B.H.P. If  $e_1$  is the efficiency of the dynamo, B.H.P. = E.H.P.  $\div$   $e_1$ . If  $e_2$  is the mechanical efficiency of the engine, the indicated horse-power, I.H.P. = brake H.P.  $\div$   $e_2$  = E.H.P.  $\div$  ( $e_1 \times e_2$ ).

If  $e_1$  and  $e_2$  each =  $91\frac{1}{2}\%$ , I.H.P. = E.H.P.  $\times$  1.194 = kw.  $\times$  1.60. In direct-connected units of 250 kw. or less the rated H.P. of the engine is commonly taken as 1.6  $\times$  the rated kw. of the generator.

Electric motors are rated at the H.P. given out at the pulley or belt. H.P. of motor = E.H.P. supplied  $\div$  efficiency of motor.

**Heat Generated by a Current.**—Joule's law shows that the heat developed in a conductor is directly proportional. 1st, to its resistance; 2d, to the square of the current strength; and 3d, to the time during which the current flows, or  $H = I^2Rt$ . Since  $I = E \div R$ ,

$$I^2Rt = \frac{E}{R} IRt = EIt = E \frac{E}{R} t = \frac{E^2t}{R}.$$

Or, heat = current<sup>2</sup>  $\times$  resistance  $\times$  time  
 = electro-motive force  $\times$  current  $\times$  time  
 = electro-motive force<sup>2</sup>  $\times$  time  $\div$  resistance.

$Q$  = quantity of electricity flowing =  $It = (Et \div R)$ .  
 $H = EQ$ ; or heat = electro-motive force  $\times$  quantity.

The electro-motive force here is that causing the flow, or the difference in potential between the ends of the conductor.

The electrical unit of heat, or "joule" =  $10^7$  ergs = heat generated in one second by a current of 1 ampere flowing through a resistance of one ohm = .239 gramme of water raised  $1^\circ$  C.  $H = I^2Rt \times .239$  gramme calories =  $I^2Rt \times .0009478$  British thermal units.

In electric lighting the energy of the current is converted into heat in the lamps. The resistance of the lamp is made great so that the required quantity of heat may be developed, while in the wire leading to and from the lamp the resistance is made as small as is commercially practicable, so that as little energy as possible may be wasted in heating the wire.

**Heating of Conductors.** (From Kapp's Electrical Transmission of Energy.)—It becomes a matter of great importance to determine before-

hand what rise in temperature is to be expected in each given case, and if that rise should be found to be greater than appears safe, provision must be made to increase the rate at which heat is carried off. This can generally be done by increasing the superficial area of the conductor. Say we have one circular conductor of 1 square inch area, and find that with 1000 amperes flowing it would become too hot. Now by splitting up this conductor into 10 separate wires each one tenth of a square inch cross-sectional area, we have not altered the total amount of energy transformed into heat, but we have increased the surface exposed to the cooling action of the surrounding air in the ratio of 1 :  $\sqrt{10}$ , and therefore the ten thin wires can dissipate more than three times the heat, as compared with the single thick wire.

Prof. Forbes states that an insulated wire carries a greater current without overheating than a bare wire if the diameter be not too great. Assuming the diameter of the cable to be twice the diam. of the conductor, a greater current can be carried in insulated wires than in bare wires up to 1.9 inch diam. of conductor. If diam. of cable = 4 times diam. of conductor, this is the case up to 1.1 inch diam. of conductor.

**Heating of Bare Wires.**—The following formulæ are given by Kennelly:

$$T = \frac{I^2}{d^3} \times 90,000 + t; \quad d = 44.8 \sqrt[3]{\frac{I^2}{T - t}}$$

$T$  = temperature of the wire and  $t$  that of the air, in Fahrenheit degrees;  
 $I$  = current in amperes,  $d$  = diameter of the wire in mils.

If we take  $T - t = 90^\circ \text{ F.}$ ,  $\sqrt[3]{90} = 4.48$ , then

$$d = 10 \sqrt[3]{I^2} \quad \text{and} \quad I = \sqrt{d^3 \div 1,000}.$$

This latter formula gives for the carrying capacity in amperes of bare wires almost exactly the figures given for weather-proof wires in the Fire Underwriters' table except in the case of Nos. 18 and 16, B. & S. gauge, for which the formula gives 8 and 11 ampere, respectively, instead of 5 and 8 amperes, given in the table.

**Heating of Coils.**—The rise of temperature in magnet coils due to the passage of current through the wire is approximately proportional to the watts lost in the coil per unit of effective radiating surface, thus:

$$t \propto \frac{I^2 R}{S}, \quad \text{or} \quad t = \frac{I^2 R}{kS},$$

$t$  being the temperature rise in degrees Fahr.;  $S$ , the effective radiating surface; and  $k$  a coefficient which varies widely, according to conditions. In electromagnet coils of small size and power,  $k$  may be as large as 0.015. Ordinarily it ranges from 0.012 down to 0.005; a fair average is 0.007. The more exposed the coil is to air circulation, the larger is the value of  $k$ ; the larger the proportion of iron to copper, by weight, in the core and winding, the thinner the winding with relation to its dimension parallel with the magnet core, and the larger the "space factor" of the winding, the larger will be the value of  $k$ . The space factor is the ratio of the actual copper cross-section of the whole coil to the gross cross-section of copper, insulation, and interstices.

See also the discussion of magnet windings under Electromagnets, p. 1050.

**Fusion of Wires.**—W. H. Preece gives a formula for the current required to fuse wires of different metals, viz.,  $I = ad^{\frac{3}{2}}$ , in which  $d$  is the diameter in inches and  $a$  a coefficient whose value for different metals is as follows: Copper, 10244; aluminum, 7585; platinum, 5172; German silver, 5230; platinumoid, 4750; iron, 3148; tin, 1462; lead, 1379; alloy of 2 lead and 1 tin, 1318.

**Allowable Carrying Capacity of Copper Wires.**

(Fire Underwriters' Rules.)

B. & S. Gauge.	Circular Mils.	Amperes.		Circular Mils.	Amperes

00	133,100	150	220	1,600,000	890	1,430
000	167,800	177	262	1,800,000	970	1,550
0000	211,600	210	312	2,000,000	1,050	1,670

For insulated aluminum wire the safe-carrying capacity is 84 per cent of that of copper wire with the same insulation.

**Underwriters' Insulation.**—The thickness of insulation required by the rules of the National Board of Fire Underwriters varies with the size of the wire, the character of the insulation, and the voltage. The thickness of insulation on rubber-covered wires carrying voltages up to 600 varies from  $\frac{3}{16}$  inch for a No. 18 B. & S. gauge wire to  $\frac{1}{8}$  inch for a wire of 1 000 000 circular mils. Weather-proof insulation is required to be slightly thicker. For voltages of over 600 the insulation is required to be at least  $\frac{1}{16}$  inch thick for all sizes of wire under No. 8 B. & S. gauge, and to be at least  $\frac{3}{32}$  inch thick for all sizes greater than No. 0000 B. & S. gauge.

**Copper-wire Table.**—The table on pages 1034 and 1035 is abridged from one computed by the Committee on Units and Standards of the American Institute of Electrical Engineers (Trans. Oct. 1893).

**ELECTRIC TRANSMISSION, DIRECT CURRENTS.****Cross-section of Wire Required for a Given Current.**—

Let  $R$  = resistance of a given line of copper wire, in ohms;

$r$  = " " " 1 mil-foot of copper;

$L$  = length of wire, in feet;

$e$  = drop in voltage between the two ends;

$I$  = current, in amperes;

$A$  = sectional area of wire, in circular mils;

then  $I = \frac{e}{R}$ ;  $R = \frac{e}{I}$ ;  $R = r \frac{L}{A}$ ; whence  $A = \frac{rIL}{e}$ .

The value of  $r$  for soft copper wire at 75° F. is 10.505 international ohms. For ordinary drawn copper wire the value of 10.8 is commonly taken, corresponding to a conductivity of 97.2 per cent.

For a circuit, going and return, the total length is  $2L$ , and the formula becomes  $A = 21.6IL \div e$ ,  $L$  here being the distance from the point of supply to the point of delivery.

If  $E$  is the voltage at the generator and  $a$  the per cent of drop in the line, then  $e = Ea \div 100$ , and  $A = \frac{2160IL}{aE}$ .

If  $P$  = the power in watts, =  $EI$ , then  $I = \frac{P}{E}$ , and  $A = \frac{2160PL}{aE^2}$ .

If  $P_k$  = the power in kilowatts,  $A$

**Weights, Lengths, and Resistances of Cool, Warm, and Hot Copper Wires.**

Gauges.		Diam-eter, inches.	Area, Circular mils.	Weight.		Length.		Resistance in International Ohms.

If  $L_m$  = the distance in miles, and  $A_c$  the area in circular inches,  $A_c = 6405 P_k L_m \div aE^2$ . If  $A_s$  = area in square inches  $A_s = 5030 P_k L_m \div aE^2$ . When the area in circular mils has been determined by either of these formulæ reference should be made to the table of Allowable Capacity of Wires, to see if the calculated size is sufficient to avoid overheating. For all interior wiring the rules of the National Board of Fire Underwriters should be followed. See Appendix to Vol. II of Crocker's Electric Lighting.

**Weight of Copper for a Given Power.**—Taking the weight of a mil-foot of copper at .000003027 lb., the weight of copper in a circuit of length  $2L$  and cross-section  $A$ , in circ. mils, is  $0.000006054LA$  lbs., =  $W$ . Substituting for  $A$  its value  $2160PL \div aE^2$  we have

$$W = 0.0130766PL^2 \div aE^2; \quad P \text{ in watts, } L \text{ in ft.}$$

$$W = 13.0766 P_k L^2 \div aE^2; \quad P_k \text{ in kilowatts, } L \text{ in ft.}$$

$$W = 364,556,000 P_k L^2 m \div aE^2; \quad P_k \text{ in kilowatts, } L_m \text{ in miles.}$$

The weight of copper required varies directly as the power transmitted; inversely as the percentage of drop or loss; directly as the square of the distance; and inversely as the square of the voltage.

From the last formula the following table has been calculated.

WEIGHT OF COPPER WIRE TO CARRY 1000 KILOWATTS WITH 10% LOSS.

Distance in miles.	1	5	10	20	50	100
Volts.	Weight in lbs.					
500	145,822	3,645,560				
1,000	36,456	911,390	3,645,560			
2,000	9,114	227,848	911,390	3,645,560		
5,000	1,458	36,456	145,822	593,290	3,645,560	
10,000	365	9,114	36,456	145,822	911,390	3,645,560
20,000	91	2,278	9,114	36,456	227,848	911,390
40,000	.....	570	2,278	9,114	56,962	227,848
60,000	.....	.....	1,013	4,051	25,316	101,266

In calculating the distance, an addition of about 5 per cent should be made for sag of the wires.

**Short-circuiting.**—From the law  $I = \frac{E}{R}$  it is seen that with any pressure  $E$ , the current  $I$  will become very great if  $R$  is made very small. In short-circuiting the resistance becomes small and the current therefore great. Hence the dangers of short-circuiting a current.

**Economy of Electric Transmission.**—Lord Kelvin's rule for the most economical section of conductor is that for which the annual interest on capital outlay is equal to the annual cost of energy wasted.

Tables have been compiled by Professor Forbes and others in accordance with modifications of this rule. For a given entering horse-power the question is merely one as to what current density, or how many amperes per square inch of conductor, should be employed. Kelvin's rule gives about 393 amperes per square inch, and Professor Forbes's tables give a current density of about 380 amperes per square inch as most economical.

Bell (Electric Transmission of Power) shows that while Kelvin's rule correctly indicates the condition of minimum cost in transmission for a given current and line, it omits many practical considerations and is inapplicable to most power transmission work. Each plant has to be considered on its merits and very various conditions are likely to determine the line loss in different cases. Several cases are cited by Bell to show that neither Kelvin's law nor any modification of it is a safe guide in determining the proper allowance for loss of energy in the line.

**Wire Tables.**—The tables on the following page show the relation between load, distance, and "drop" or loss by voltage in a two-wire circuit of any standard size of wire. The tables are based on the formula

$$(21.6IL) \div A = \text{Drop in volts.}$$

$I$  = current in amperes,  $L$  = distance in feet from point of supply to point of delivery. The factors  $I$  and  $L$  are combined in the table, in the compound factor "ampere feet."

WIRE TABLE—RELATION BETWEEN LOAD, DISTANCE, LOSS, AND SIZE OF CONDUCTOR.

**Table I.—110-volt and 220-volt Two-Wire Circuits.**

NOTE.—The numbers in the body of the tables are Ampere-Feet; *i.e.*, Amperes × Distance (length of one wire) in feet. See examples on next page.

EXAMPLES IN THE USE OF THE WIRE TABLES.—1. Required the maximum load in amperes at 220 volts that can be carried 95 feet by No. 6 wire without exceeding  $1\frac{1}{2}\%$  drop.

Find No. 6 in the 220-volt column of Table I; opposite this in the  $1\frac{1}{2}\%$  column is the number 4005, which is the ampere-feet. Dividing this by the required distance (95 feet), gives the load, 42.15 amperes.

*Example 2.* A 500-volt line is to carry 100 amperes 600 feet with a drop not exceeding 5%; what size of wire will be required?

The ampere-feet will be  $100 \times 600 = 60,000$ . Referring to the 5% column of Table II, the nearest number of ampere-feet is 60,750, which is opposite No. 3 wire in the 500-volt column.

These tables also show the percentage of the power delivered to a line that is lost in non-inductive alternating-current circuits. Such circuits are obtained when the load consists of incandescent lamps and the circuit wires lie only an inch or two apart, as in conduit wiring.

**Efficiency of Long-distance Transmission.** (F. R. Hart, *Power*, Feb. 1892.)—The mechanical efficiency of a system is the ratio of the power delivered to the dynamo-electric machines at one end of the line to the power delivered by the electric motors at the distant end. The commercial efficiency of a dynamo or motor varies with its load. Under the most favorable conditions we must expect a loss of say 9% in the dynamo and 9% in the motor. The loss in transmission, due to fall in electrical pressure or "drop" in the line, is governed by the size of the wires, the other conditions remaining the same. For a long-distance transmission plant this will vary from 5% upwards. With a loss of 5% in the line the total efficiency of transmission will be slightly under 79%. With a loss of 10% in the line it will be slightly under 75%. We may call 80% the practical limit of the efficiency with the apparatus of to-day. The methods for long-distance transmission may be divided into three general classes: (1) continuous current; (2) alternating current; and (3) regenerating or "motor-dynamo" systems.

There are many factors which govern the selection of a system. For each problem considered there will be found certain fixed and certain unfixed conditions. In general the fixed factors are: (1) capacity of source of power; (2) cost of power at source; (3) cost of power by other means at point of delivery; (4) danger considerations at motors; (5) operating conditions; (6) construction conditions (length of line, character of country, etc.). The partly fixed conditions are: (7) power which must be delivered, i.e., the efficiency of the system; (8) size and number of delivery units. The variable conditions are: (9) initial voltage; (10) pounds of copper on line; (11) original cost of all apparatus and construction; (12) expenses, operating (fixed charges, interest, depreciation, taxes, insurance, etc.); (13) liability of trouble and stoppages; (14) danger at station and on line; (15) convenience in operating, making changes, extensions, etc.

The relative advantages of different systems vary with each particular transmission problem, but in a general way may be tabulated as below:

	System.	Advantages.	Disadvantages.
Continuous.	2-wire { Low voltage. High voltage.	Safety, simplicity.	Expense for copper.
		Economy, simplicity.	Danger; difficulty of building machines.
	3-wire.	Low voltage on machines and saving in copper.	Not saving enough in copper for long distances. Necessity for "balanced" system.
Alternating.	Multiple-wire.	Low voltage at machines and saving in copper.	
	Single phase.	Economy of copper.	Cannot start under load. Low efficiency.
	Multiphase.	Economy of copper, synchronous speed unnecessary; applicable to very long distances.	Requires more than two wires.
	Motor-dynamo.	High-voltage transmission. Low-voltage delivery.	Expensive. Low efficiency.

**TABLE OF ELECTRICAL HORSE-POWERS.**

Formula :  $\frac{\text{Volts} \times \text{Amperes}}{746} = \text{H.P.}, \text{ or } 1 \text{ volt-ampere} = .0013405 \text{ H.P.}$

Read amperes at top and volts at side, or *vice versa*.

Amperes or Volts.	Volts or Amperes.

**Cost of Copper for Long-distance Transmission.**

(Westinghouse El. & Mfg. Co.)

COST OF COPPER REQUIRED FOR THE DELIVERY OF ONE MECHANICAL HORSE-POWER AT MOTOR SHAFT WITH 1000, 2000, 3000, 4000, 5000, and 10,000 VOLTS AT MOTOR TERMINALS, OR AT TERMINALS OF LOWERING TRANSFORMERS.

Loss of energy in conductors (drop) equals 20%. Motor efficiency, 90%. Length of conductor per mile of single distance, 11,000 ft., to allow for sag. Cost of copper taken at 16 cents per pound.

**Systems of Electrical Distribution in Common Use.****I. DIRECT CURRENT.****A. Constant Potential.**

110 to 125 and 220 to 250 Volts.—Distances less than, say, 1500 feet.

For incandescent lamps.

For arc-lamps, usually 2 in series.

For motors of moderate sizes.

200 to 250 and 440 Volts, 3-wire.—Distances less than, say, 5000 feet.

For incandescent lamps.

For arc-lamps, usually 2 in series on each branch.

For motors 110 or 220 volts, usually 220 volts.

500 Volts.—Distances less than, say, 20,000 feet.

Incidentally for arc-lamps, usually 10 in series.

For motors, stationary and street-car.

**B. Constant Current.**

Usually 5,  $6\frac{1}{2}$ , or  $9\frac{1}{2}$  amperes, the volts increasing to several thousand, as demanded, for arc-lamps.

**II. ALTERNATING CURRENT.****A. Constant Potential.**

For incandescent lamps, arc-lamps, and motors.

Ployphase Systems.

For arc and incandescent lamps, motors, and rotary converters for giving direct current.

Ployphase—2- and 3-phase—high tension (25,000 volts and over), for long-distance transmission; transformed by step-up and step-down transformers.

**B. Constant Current.**

Usually 5 to 6.6 amperes. For arc-lamps.

**References on Power Distribution.**—Abbott, Electric Transmission of Energy; Bell, Electric Power Transmission; Cushing, Standard Wiring for Incandescent Light and Power; Crocker, Electric Lighting, 2 vols.; Poole, Electric Wiring.

**ELECTRIC RAILWAYS.**

Space will not admit of a proper treatment of this subject in this work. Consult Crosby and Bell, The Electric Railway in Theory and Practice; Fairchild, Street Railways; Merrill, Reference Book of Tables and Formulæ for Street Railway Engineers; Bell, Electric Transmission of Power; Dawson, Engineering and Electric Traction Pocket-book.

**ELECTRIC LIGHTING.**

**Arc Lights.**—*Direct-current open arcs* usually require about 10 amperes at 45 volts, or 450 watts. The range of voltage is from 42 to 52 for ordinary arcs. The most satisfactory light is given by 45 to 47 volts. Search-light projectors use from 50 to 100 amperes at 48 to 53 volts.

The *candle-power* of an arc light varies according to the direction in which the light is measured; thus we have, 1, mean horizontal candle-power; 2, maximum candle-power, which is usually found at an angle below the horizontal; 3, mean spherical candle-power; 4, mean hemispherical candle-power, below the horizontal.

The nominal candle-power of an arc lamp is an arbitrary figure. A 450-watt arc is commonly called 2000 c.-p. and a 300-watt arc is 1200 c.-p. These figures greatly exceed the true candle-power. Carhart found with an arc of 10 amperes and 45 volts a maximum c.-p. of 450, but with the same watts 8.4 amperes, and 54 volts he obtained 900 c.-p. Blondel, however, found the c.-p. a maximum usually below 45 volts. Crocker explains the discrepancy as probably due to a difference in size and quality of the carbons.

Current for arc lighting is furnished either on the series constant current, or on the parallel constant potential system. In the latter the voltage of the circuit is usually 110 and two lamps are connected in series. In currents with higher voltages more lamps are used in series; for instance 10 with a 500-volt circuit.

*Enclosed Arcs*—Direct current enclosed arcs consume about 5 amperes at 80 volts, or 400 watts. The chief advantages of the enclosed arcs, on constant potential circuits are the long life of the carbons, 100 to 150 hours, as compared with 8 to 10 hours for open arcs; simplicity of construction, absence of sparks, agreeable quality and better distribution of light.

Alternating-current enclosed arcs usually take a current of 6 amperes at 70 or 75 volts. With 70 volts and 6 amperes, in a 104-volt circuit, the apparent watts at the lamp terminals are 625 and at the arc 420, the actual watts being 445 and 390 respectively. The watts consumed in the inductive resistance average 35 to 45.

**Incandescent Lamps.**—Candle-power of nominal 16 c.p. 110-volt lamp;

Mean horizontal 15.7 to 16.6

Mean spherical 12.7 to 13.8

Mean hemispherical 14.0 to 14.6

Mean within 30° from tip 7.9 to 10.9

Ordinary lamps take from 3 to 4 watts per candle-power. A 16 candle-power lamp using 3.5 watts per candle-power or 56 watts at 110 volts takes a current of  $56 \div 110 = 0.51$  ampere. For a given efficiency or watts per candle-power the current and the power increase directly as the candle-power. An ordinary lamp taking 56 watts, 13 lamps take 1 H.P. of electrical energy, or 18 lamps 1.008 kilowatts.

**Variation in Candle-Power, Efficiency, and Life.**—The following table shows the variation in candle-power, etc., of the General Electric Co.'s standard 100 to 125 volts, 3.1 and 3.5 watt lamps, due to variation in voltage supplied to them. It will be seen that if a 3.1 watt lamp is run at 10 per cent below its normal voltage, it may have over 9 times as long a life, but it will give only 53 per cent of its normal lighting power, and the light will cost 50 per cent more in energy per candle-power. If it is run at 6 per cent above its normal voltage, it will give 37 per cent more light, will take nearly 20 per cent less energy for equal light power, but it will have less than one third of its normal life.

Per cent of Normal Voltage.	Per cent of Normal Candle-power.	Efficiency in watts per Candle, 3.1 watt Lamp.	Relative Life. 3.1 watt Lamp.	Efficiency in watts per Candle, 3.5 watts.	Relative Life. 3.5 watts.
90	53	4.65	9.41	5.36	
91	57	4.44	7.16	5.09	
92	61	4.24	5.55	4.85

95	74	3.75	2.75	4.26	3.10
96	79	3.60	2.20	4.09	2.47
97	84	3.45	1.79	3.93	1.95
98	89	3.34	1.46	3.78	1.53
99	94.5	3.22	1.21	3.64	1.26
100	100	3.10	1.00	3.50	1.00
101	106	2.99	.818	3.38	.84
102	112	2.90	.681	3.27	.68
103	118	2.80	.562	3.16	.58
104	124	2.70	.452	3.05	.47
105	130	2.62	.374	2.95	.39
106	137	2.54	.310	2.85	.31

The candle-power of a lamp falls off with its length of life, so that during the latter half of its life it has only 60 per cent or 70 per cent of its rated candle-power, and the watts per candle-power are increased 60 per cent or 70 per cent. After a lamp has burned for 500 or 600 hours it is more economical to break it and supply a new one if the price of electrical energy is that usually charged by central stations.

**Specifications for Lamps.** (Crocker.)—The initial candle-power of any lamp at the rated voltage should not be more than 9 per cent above or below the value called for. The average candle-power of a lot should be within 6 per cent of the rated value. The standard efficiencies are 3.1, 3.5, and 4 watts per candle-power. Each lamp at rated voltage should take within 6 per cent of the watts specified, and the average for the lot should be within 4 per cent. The useful life of a lamp is the time it will burn before falling to a certain candle-power, say 80 per cent of its initial candle-power. For 3.1 watt lamps the useful life is about 400 to 450 hours, for 3.5 watt lamps about 800, and 4 watt lamps about 1600 hours.

**Special Lamps.**—The ordinary 16 c.-p. 110-volt is the standard for interior lighting. Thousands of varieties of lamps for different voltages and candle-power are made for special purposes, from the primary lamp, supplied by primary batteries using three volts and about 1 ampere and giving  $\frac{1}{2}$  c.-p., and the  $\frac{3}{4}$  c.-p. bicycle lamp, 4 volts and 0.5 ampere, to lamps of 100 c.p. at 220 volts. Series lamps of 1 c.-p. are used in illuminating signs,  $\frac{2}{3}$  ampere and 12.5 to 15 volts, eight lamps being used on a 110-volt circuit. Standard sizes for different voltages, 50, 110, or 220, are 8, 16, 24, 32, 50, and 100 c.-p.

**Nernst Lamp.**—A form of incandescent lamp originated by Dr. Walther Nernst, of Göttingen, is being developed in this country by the Nernst Lamp Company, Pittsburg, Pa. It depends for its operation upon the peculiar property of certain rare earths, such as yttrium, thorium, zirconium, etc., of becoming electrical conductors when heated to a certain temperature; when cold, these oxides are non-conductors. The lamp comprises a "glower" composed of rare earths mixed with a binding material and pressed into a small rod; a heater for bringing the glower up to the conducting temperature; an automatic cut-out for disconnecting the heater when the glower lights up, and a "ballast" consisting of a small resistance coil of wire having a positive temperature-resistance coefficient. The ballast is connected in series with the glower; its presence is required to compensate the negative temperature-resistance coefficient of the glower; without the ballast, the resistance of the glower would become lower and lower as its temperature rose, until the flow of current through it would destroy it. Fig. 171a shows the elementary circuits of a simple Nernst lamp. The cut-out is an electromagnet connected in series with the glower. When current begins to flow through the glower, the magnet pulls up the armature lying across the contacts of the cut-out, thereby cutting out the heater. The heater is a coil of fine wire either located very near the glower or encircling it. The glower is from  $\frac{1}{32}$  to  $\frac{1}{16}$  inch in diameter and about 1 inch long.

The material of the glower is an electrolyte, so that this type of lamp is not well adapted for operation on direct-current circuits because of the wasting away at the positive end and the deposition of material at the negative end.

The lamps are made with one glower, or with two, three, or six glowers connected in parallel, and for operation on 100 to 120 and 200 to 240 volt circuits.

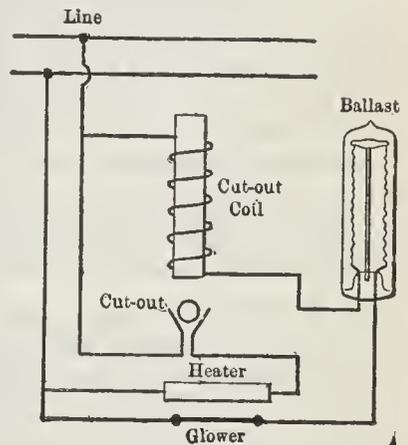

FIG. 171a.

**ELECTRIC WELDING.**

The apparatus most generally used consists of an alternating-current dynamo, feeding a comparatively high-potential current to the primary coil of an induction-coil or transformer, the secondary of which is made so large in section and so short in length as to supply to the work currents not exceeding two or three volts, and of very large volume or rate of flow. The welding clamps are attached to the secondary terminals. Other forms of apparatus, such as dynamos constructed to yield alternating currents direct from the armature to the welding-clamps, are used to a limited extent.

The conductivity for heat of the metal to be welded has a decided influence on the heating, and in welding iron its comparatively low heat conduction assists the work materially. (See papers by Sir F. Bramwell, Proc. Inst. C. E., part iv., vol. cii. p. 1; and Elihu Thomson, Trans. A. I. M. E., xix. 877.)

Fred. P. Royce, *Iron Age*, Nov. 28, 1892, gives the following figures showing the amount of power required to weld axles and tires:

**AXLE-WELDING.**

	Seconds.
1-inch round axle requires 25 H.P. for.....	45
1-inch square axle requires 30 H.P. for.....	48
1¼-inch round axle requires 35 H.P. for.....	60
1¼-inch square axle requires 40 H.P. for.....	70
2-inch round axle requires 75 H.P. for.....	95
2-inch square axle requires 90 H.P. for.....	100

The slightly increased time and power required for welding the square axle is not only due to the extra metal in it, but in part to the care which it is best to use to secure a perfect alignment.

**TIRE-WELDING.**

	Seconds.
1 × 3/16-inch tire requires 11 H.P. for.....	15
1¼ × 3/8-inch tire requires 23 H.P. for.....	25
1½ × 3/8-inch tire requires 20 H.P. for.....	30
1½ × 1/2-inch tire requires 23 H.P. for.....	40
2 × 1/2-inch tire requires 29 H.P. for.....	55
2 × 3/4-inch tire requires 42 H.P. for.....	62

The time above given for welding is of course that required for the actual application of the current only, and does not include that consumed by placing the axles or tires in the machine, the removal of the upset and other finishing processes. From the data thus submitted, the cost of welding can be readily figured for any locality where the price of fuel and cost of labor are known.

In almost all cases the cost of the fuel used under the boilers for producing power for electric welding is practically the same as the cost of fuel used in forges for the same amount of work, taking into consideration the difference in price of fuel used in either case.

Prof. A. B. W. Kennedy found that 2½-inch iron tubes ¼ inch thick were welded in 61 seconds, the net horse-power required at this speed being 23.4 (say 33 indicated horse-power) per square inch of section. Brass tubing required 21.2 net horse-power. About 60 total indicated horse-power would be required for the welding of angle-irons 3 × 3 × ½ inch in from two to three minutes. Copper requires about 80 horse-power per square inch of section, and an inch bar can be welded in 25 seconds. It takes about 90 seconds to weld a steel bar 2 inches in diameter.

**ELECTRIC HEATERS.**

Wherever a comparatively small amount of heat is desired to be automatically and uniformly maintained, and started or stopped on the instant without waste, there is the province of the electric heater.

The elementary form of heater is some form of resistance, such as coils of thin wire introduced into an electric circuit and surrounded with a substance, which will permit the conduction and radiation of heat, and at the same time serve to electrically insulate the resistance.

This resistance should be proportional to the electro-motive force of the current used and to the equation of Joule's law :

$$H = I^2 R t \times 0.24,$$

where  $I$  is the current in amperes;  $R$ , the resistance in ohms;  $t$ , the time in seconds; and  $H$ , the heat in gram-centigrade units.

Since the resistance of metals increases as their temperature increases, a thin wire heated by current passing through it will resist more, and grow hotter and hotter until its rate of loss of heat by conduction and radiation equals the rate at which heat is supplied by the current. In a short wire, before heat enough can be dispelled for commercial purposes, fusion will begin; and in electric heaters it is necessary to use either long lengths of thin wire, or carbon, which alone of all conductors resists fusion. In the majority of heaters, coils of thin wire are used, separately embedded in some substance of poor electrical but good thermal conductivity.

The Consolidated Car-heating Co.'s electric heater consists of a galvanized iron wire wound in a spiral groove upon a porcelain insulator. Each heater is  $30\frac{5}{8}$  in. long,  $8\frac{7}{8}$  in. high, and  $6\frac{5}{8}$  in. wide. Upon it is wound 392 ft. of wire. The weight of the whole is  $231\frac{1}{2}$  lbs.

Each heater is designed to absorb 1000 watts of a 500-volt current. Six heaters are the complement for an ordinary electric car. For ordinary weather the heaters may be combined by the switch in different ways, so that five different intensities of heating-surface are possible, besides the position in which no heat is generated, the current being turned entirely off.

For heating an ordinary electric car the Consolidated Co. states that from 2 to 12 amperes on a 500-volt circuit is sufficient. With the outside temperature at  $20^\circ$  to  $30^\circ$ , about 6 amperes will suffice. With zero or lower temperature, the full 12 amperes is required to heat a car effectively.

Compare these figures with the experience in steam-heating of railway-cars, as follows:

1 B.T.U. = 0.29084 watt-hours.

6 amperes on a 500-volt circuit = 3000 watts.

A current consumption of 6 amperes will generate  $3000 \div 0.29084 = 10,315$  B.T.U. per hour.

In steam-car heating, a passenger coach usually requires from 60 lbs. of steam in freezing weather to 100 lbs. in zero weather per hour. Supposing the steam to enter the pipes at 20 lbs. pressure, and to be discharged at  $200^\circ$  F., each pound of steam will give up 983 B.T.U. to the car. Then the equivalent of the thermal units delivered by the electrical-heating system in pounds of steam, is  $10,315 \div 983 = 10\frac{1}{2}$ , nearly.

Thus the Consolidated Co.'s estimates for electric-heating provide the equivalent of  $10\frac{1}{2}$  lbs. of steam per car per hour in freezing weather and 21 lbs. in zero weather.

Suppose that by the use of good coal, careful firing, well designed boilers, and triple-expansion engines we are able in daily practice to generate 1 H.P. delivered at the fly-wheel with an expenditure of  $2\frac{1}{2}$  lbs. of coal per hour.

We have then to convert this energy into electricity, transmit it by wire to the heater, and convert it into heat by passing it through a resistance-coil. We may set the combined efficiency of the dynamo and line circuit at 85%, and will suppose that all the electricity is converted into heat in the resistance-coils of the radiator. Then 1 brake H.P. at the engine = 0.85 electrical H.P. at the resistance-coil = 1,683,000 ft.-lbs. energy per hour = 2180 heat-units. But since it required  $2\frac{1}{2}$  lbs. of coal to develop 1 brake H.P., it follows that the heat given out at the radiator per pound of coal burned in the boiler furnace will be  $2180 \div 2\frac{1}{2} = 872$  H.U. An ordinary steam-heating system utilizes 9652 H.U. per lb. of coal for heating; hence the efficiency of the electric system is to the efficiency of the steam-heating system as 872 to 9652, or about 1 to 11. (*Eng'g News*, Aug. 9, '90; Mar. 30, '92; May 15, '93.)

## ELECTRICAL ACCUMULATORS OR STORAGE-BATTERIES.

The original, or Planté, storage battery consisted of two plates of metallic lead immersed in a vessel containing sulphuric acid. An electric current being sent through the cell the surface of the positive plate was converted into peroxide of lead,  $PbO_2$ . This was called charging the cell. After being thus charged the cell could be used as a source of electric current, or discharged. Planté and other authorities consider that in charging,  $PbO_2$  is formed on the positive plate and spongy metallic lead on the negative, both being con-

verted into lead oxide, PbO, by the discharge, but others hold that sulphate of lead is made on both plates by discharging and that during the charging PbO<sub>2</sub> is formed on the positive plate and metallic Pb on the other, sulphuric acid being set free.

The acid being continually abstracted from the electrolyte as the discharge proceeds, the density of the solution becomes less. In the charging operation this action is reversed, the acid being reinstated in the liquid and therefore causing an increase in its density.

The difference of potential developed by lead and lead peroxide immersed in dilute H<sub>2</sub>SO<sub>4</sub> is about two volts. A lead-peroxide plate gradually loses its electrical energy by local action, the rate of such loss varying according to the circumstances of its preparation and the condition of the cell.

In the Faure or pasted cells lead plates are coated with minium or litharge made into a paste with acidulated water. When dry these plates are placed in a bath of dilute H<sub>2</sub>SO<sub>4</sub> and subjected to the action of the current, by which the oxide on the positive plate is converted into peroxide and that on the negative plate reduced to finely divided or porous lead.

The initial electro-motive force of the Faure cell averages 2.25 volts, but after being allowed to rest some little time it is reduced to about 2.0 volts.

The "chloride" accumulator, made by the Electric Storage Battery Co., of Philadelphia, consists of lead plates containing cells filled with spongy lead or with lead peroxide. The spongy lead is formed by first casting into the lead plate pastilles of a mixture of lead and zinc chlorides, the lead in which is afterwards by an electrolytic method converted into spongy lead, while the zinc chloride is dissolved and washed away. Plates intended for positive plates have the spongy lead converted into peroxide by immersing them in sulphuric acid and passing a current through them in one direction for about two weeks.

The following tables give the elements of several sizes of "chloride" accumulators. Type G is furnished in cells containing 11-125 plates, and type H from 21 plates to any greater number desired. The voltage of cells of all sizes is slightly above two volts on open circuit, and during discharge varies from that point at the beginning to 1.8 at the end.

Accumulators are largely used in central lighting and power stations, in office buildings and other large isolated plants, for the purpose of absorbing the energy of the generating plant during times of light load, and for giving it out during times of heavy load or when the generating plant is idle. The advantages of their use for such purposes are thus enumerated:

1. Reduction in coal consumption and general operating expenses, due to the generating machinery being run at the point of greatest economy while in service, and being shut down entirely during hours of light load, the battery supplying the whole of the current.

\* D = addition per plate from 25 to 125 plates; approximate as to dimensions and weights.

2. The possibility of obtaining good regulation in pressure during fluctuations in load, especially when the day load consists largely of elevators and similar disturbing elements.

3. To meet sudden demands which arise unexpectedly, as in the case of darkness caused by storm or thunder-showers; also in case of emergency due to accident or stoppage of generating-plant.

4. Smaller generating-plant required where the battery takes the peak of the load, which usually only lasts for a few hours, and yet where no battery is used necessitates sufficient generators, etc., being installed to provide for the maximum output, which in many cases is about double the normal output.

**The Working Current, or Energy Efficiency,** of a storage-cell is the ratio between the value of the current or energy expended in the charging operation, and that obtained when the cell is discharged at any specified rate.

In a lead storage-cell, if the surface and quantity of active material be accurately proportioned, and if the discharge be commenced immediately after the termination of the charge, then a current efficiency of as much as 98% may be obtained, provided the rate of discharge is low and well regulated. In practice it is found that low rates of discharge are not economical, and as the current efficiency always decreases as the discharge rate increases, it is found that the normal current efficiency seldom exceeds 90%, and averages about 85%.

As the normal discharging electro-motive force of a lead secondary cell never exceeds 2 volts, and as an electro-motive force of from 2.4 to 2.5 volts is required at its poles to overcome both its opposing electro-motive force and its internal resistance, there is an initial loss of 20% between the energy required to charge it and that given out during its discharge.

As the normal discharging potential is continually being reduced as the rate of discharge increases, it follows that an energy efficiency of 80% can never be realized. As a matter of fact, a maximum of 75% and a mean of 60% is the usual energy efficiency of lead-sulphuric-acid storage-cells.

**Important General Rules.**—Storage cells should not be allowed to stand idle when charged, and must not stand idle when uncharged or after being discharged. If a battery is to be put out of commission for any length of time, it should be fully charged, the electrolyte all drawn off, the cells filled with pure water and then discharged slightly—say until the E.M.F. is 1.95 volts. The cells should then be emptied, and the plates dried in a warm atmosphere.

In mixing the electrolyte, the acid should always be poured into the water. The mixing must be very gradual in order to avoid excessive heating. The acid solution must be cooled before the cells are filled with it. The acid should be tested for impurities before mixing the electrolyte.

*Tests for Impurities.*—To test for copper and arsenic, add a small quantity of dilute acid to an equal quantity of fresh sulphide of hydrogen ( $H_2S$ ). The presence of copper will cause a black precipitate; that of arsenic, a yellow precipitate.

To test for iron, add a few drops of nitric acid to a small quantity of dilute acid and heat the mixture; after cooling add a few drops of potassium sulphocyanide solution. The presence of iron will be indicated by a deep red color.

*Charging and Discharging.*—Charging should be stopped when the voltage is 2.6 volts per cell and gas is given off, except in the first charging, when 2.7 should be reached. Discharging should be stopped and the cells recharged when the voltage is down to 1.8 volts per cell when discharging at normal rate.

## ELECTROLYSIS.

The separation of a chemical compound into its constituents by means of an electric current. Faraday gave the nomenclature relating to electrolysis. The compound to be decomposed is the Electrolyte, and the process Electrolysis. The plates or poles of the battery are Electrodes. The plate where the greatest pressure exists is the Anode, and the other pole is the Cathode. The products of decomposition are Ions.

Lord Rayleigh found that a current of one ampere will deposit 0.017253 grain, or 0.001118 gramme, of silver per second on one of the plates of a silver voltameter, the liquid employed being a solution of silver nitrate containing from 15% to 20% of the salt. The weight of hydrogen similarly set free by a current of one ampere is .00001038 gramme per second.

Knowing the amount of hydrogen thus set free, and the chemical equivalents of the constituents of other substances, we can calculate what weight of their elements will be set free or deposited in a given time by a given current. Thus, the current that liberates 1 gramme of hydrogen will liberate 8 grammes of oxygen, or 107.7 grammes of silver, the numbers 8 and 107.7 being the chemical equivalents for oxygen and silver respectively.

To find the weight of metal deposited by a given current in a given time, find the weight of hydrogen liberated by the given current in the given time, and multiply by the chemical equivalent of the metal.

\* Valency is the atom-fixing or atom-replacing power of an element compared with hydrogen, whose valency is unity

† Atomic weight is the weight of one atom of each element compared with hydrogen, whose atomic weight is unity.

‡ Becquerel's extension of Faraday's law showed that the electro chemical equivalent of an element is proportional to its chemical equivalent. The latter is equal to its combining weight, and not to atomic weight ÷ valency, as defined by Thompson, Hospitalier, and others who have copied their tables. For example, the ferric salt is an exception to Thompson's rule, as are sesqui-salts in general.

Thus: Weight of silver deposited in 10 seconds by a current of 10 amperes = weight of hydrogen liberated per second × number seconds × current strength × 107.7 = .00001038 × 10 × 10 × 107.7 = .11178 gramme.

Weight of copper deposited in 1 hour by a current of 10 amperes =

$$.00001038 \times 3600 \times 10 \times 31.5 = 11.77 \text{ grammes.}$$

Since 1 ampere per second liberates .00001038 gramme of hydrogen, strength of current in amperes

$$= \frac{\text{weight in grammes of H. liberated per second}}{.00001038}$$

$$= \frac{\text{weight of element liberated per second}}{.00001038 \times \text{chemical equivalent of element}}$$

The above table (from "Practical Electrical Engineering") is calculated upon Lord Rayleigh's determination of the electro-chemical equivalents and Roscoe's atomic weights.

**ELECTRO-MAGNETS.\*****Units of Electro-magnetic Measurements.**

*Unit magnetic pole* is a pole of such strength that when placed at a distance of one centimetre from a similar pole of equal strength it repels it with a force of one dyne.

*Gauss* = unit of field strength, or density, symbol **H**, is that intensity of field which acts on a unit pole with a force of one dyne, = one line of force per square centimetre. A field of **H** units is one which acts with **H** dynes on unit pole, or **H** lines per square centimetre. A unit magnetic pole has  $4\pi$  lines of force proceeding from it.

*Maxwell* = unit of magnetic flux, is the amount of magnetism passing through every square centimetre of a field of unit density. Symbol,  $\phi$ .

*Gilbert* = unit of magneto-motive force, is the amount of M.M.F., that would be produced by a coil of  $10 \div 4\pi$  or 0.7958 ampere-turns. Symbol, **F**. The M.M.F. of a coil is equal to 1.2566 times the ampere-turns.

If a solenoid is wound with 100 turns of insulated wire carrying a current of 5 amperes, the M.M.F. exerted will be  $500 \text{ ampere-turns} \times 1.2566 = 628.3$  gilberts.

*Oersted* = unit of magnetic reluctance; it is the reluctance of a cubic centimetre of an air-pump vacuum. Symbol, **R**.

*Reluctance* is that quantity in a magnetic circuit which limits the flux under a given M.M.F. It corresponds to the resistance in the electric circuit.

*The reluctivity* of any medium is its specific reluctance, and in the C.G.S. system is the reluctance offered by a cubic centimetre of the body between opposed parallel faces. The reluctivity of nearly all substances, other than the magnetic metals, is sensibly that of vacuum, is equal to unity, and is independent of the flux density.

*Permeability* is the reciprocal of magnetic reluctivity. It is a number, and the symbol is  $\mu$ .

*Permeance* is the reciprocal of reluctance.

**Lines and Loops of Force.**—In discussing magnetic and electrical phenomena it is conventionally assumed that the attractions and repulsions as shown by the action of a magnet or a conductor upon iron filings are due to "lines of force" surrounding the magnet or conductor. The "number of lines" indicates the magnitude of the forces acting. As the iron filings arrange themselves in concentric circles, we may assume that the forces may be represented by closed curves or "loops of force." The following assumptions are made concerning the loops of force in a conductive circuit:

1. That the lines or loops of force in the conductor are parallel to the axis of the conductor.
2. That the loops of force external to the conductor are proportional in number to the current in the conductor, that is, a definite current generates a definite number of loops of force. These may be stated as the strength of field in proportion to the current.
3. That the radii of the loops of force are at right angles to the axis of the conductor.

The magnetic force proceeding from a point is equal at all points on the surface of an imaginary sphere described by a given radius about that point. A sphere of radius 1 cm. has a surface of  $4\pi$  square centimetres. If  $\phi$  = total flux, expressed as the number of lines of force emanating from a magnetic pole having a strength, **M**,

$$\phi = 4\pi M; M = \phi \div 4\pi.$$

Magnetic moment of a magnet = product of strength of pole  $M$  and its length, or distance between its poles  $L$ . Magnetic moment =  $\frac{\phi L}{4\pi}$ .

---

\* For a very full treatment of this subject see "The Electro-Magnet," published by the Varley Duplex Magnet Co., Phillipsdale, R. I.

If  $\mathbf{B}$  = number of lines flowing through each square centimetre of cross-section of a bar-magnet, or the "specific induction," and  $A$  = cross-section,

$$\text{Magnetic Moment} = LAB \div 4\pi.$$

If the bar-magnet be suspended in a magnetic field of density  $\mathbf{H}$ , and so placed that the lines of the field are all horizontal and at right angles to the axis of the bar, the north pole will be pulled forward, that is, in the direction in which the lines flow, and the south pole will be pulled in the opposite direction, the two forces producing a torsional moment or torque,

$$\text{Torque} = MLH = LABH \div 4\pi, \text{ in dyne-centimetres.}$$

Magnetic attraction or repulsion emanating from a point varies inversely as the square of the distance from that point. The law of inverse squares, however, is not true when the magnetism proceeds from a surface of appreciable extent, and the distances are small, as in dynamo-electric machines and ordinary electromagnets.

**Permeability.**—Materials differ in regard to the resistance they offer to the passage of lines of force; thus iron is more permeable than air. The permeability of a substance is expressed by a coefficient,  $\mu$ , which denotes its relation to the permeability of air, which is taken as 1. If  $\mathbf{H}$  = number of magnetic lines per square centimetre which will pass through an air-space between the poles of a magnet, and  $\mathbf{B}$  the number of lines which will pass through a certain piece of iron in that space, then  $\mu = \mathbf{B} \div \mathbf{H}$ . The permeability varies with the quality of the iron and the degree of saturation, reaching a practical limit for soft wrought iron when  $\mathbf{B}$  = about 18,000 and for cast iron when  $\mathbf{B}$  = about 10,000 C.G.S lines per square centimetre.

The permeability of a number of materials may be determined by means of the table on the following page.

**The Magnetic Circuit.**—In the electric circuit

$$\text{Current} = \frac{\text{E.M.F.}}{\text{Resistance}}, \quad \text{or} \quad I = \frac{E}{R}.$$

Similarly, in the magnetic circuit

$$\text{Magnetic Flux} = \frac{\text{Magnetomotive Force}}{\text{Reluctance}}, \quad \text{or} \quad \phi = \frac{F}{R}.$$

Reluctance is the reciprocal of permeance, and permeance is equal to permeability  $\times$  path area  $\div$  path length (metric measure); hence

$$\phi = F \frac{\mu a}{l}.$$

One ampere-turn produces 1.257 gilberts of magnetomotive force and one inch equals 2.54 centimetres; hence, in inch measure,

$$\phi = (1.257 A_t) \frac{\mu 6.45 a}{2.54 l} = \frac{3.192 \mu a A_t}{l}.$$

The ampere-turns required to produce a given magnetic flux in a given path will be

$$A_t = \frac{\phi l}{3.192 \mu a} = \frac{0.3133 \phi l}{\mu a}.$$

Since magnetic flux  $\div$  area of path = magnetic density, the ampere-turns required to produce a density  $\mathbf{B}$ , in lines of force per square inch of area of path, will be

$$A_t = 0.3133 \mathbf{B} l \div \mu.$$

This formula is used in practical work, as the magnetic density must be predetermined in order to ascertain the permeability of the material under its working conditions. When a magnetic circuit includes several

qualities of material, such as wrought iron, cast iron, and air, it is most direct to work in terms of ampere-turns per unit length of path. The ampere-turns for each material are determined separately, and the winding is designed to produce the sum of all the ampere-turns. The following table gives the average results from a number of tests made by Dr. Samuel Sheldon:

VALUES OF B AND H.

H	Ampere-turns per cent. length.	Ampere-turns per inch length.	Cast Iron.		Cast Steel.		Wrought Iron.		Sheet Metal.	
			B Kilo-gausses.	Kilomax-wells per sq. in.						
10	7.95	20.2	4.3	27.7	11.5	74.2	13.0	83.8	14.3	92.2
20	15.90	40.4	5.7	36.8	13.8	89.0	14.7	94.8	15.6	100.7
30	23.85	60.6	6.5	41.9	14.9	96.1	15.3	98.6	16.2	104.5
40	31.80	80.8	7.1	45.8	15.5	100.0	15.7	101.2	16.6	107.1
50	39.75	101.0	7.6	49.0	16.0	103.2	16.0	103.2	16.9	109.0
60	47.70	121.2	8.0	51.6	16.5	106.5	16.3	105.2	17.3	111.6
70	55.65	141.4	8.4	59.2	16.9	109.0	16.5	106.5	17.5	112.9
80	63.65	161.6	8.7	56.1	17.2	111.0	16.7	107.8	17.7	114.1
90	71.60	181.8	9.0	58.0	17.4	112.2	16.9	109.0	18.0	116.1
100	79.50	202.0	9.4	60.6	17.7	114.1	17.2	110.9	18.2	117.3
150	119.25	303.0	10.6	68.3	18.5	119.2	18.0	116.1	19.0	122.7
200	159.0	404.0	11.7	75.5	19.2	123.9	18.7	120.8	19.6	126.5
250	198.8	505.0	12.4	80.0	19.7	127.1	19.2	123.9	20.2	130.2
300	238.5	606.0	13.2	85.1	20.1	129.6	19.7	127.1	20.7	133.5

$H = 1.257$  ampere-turns per cm. = .495 ampere-turns per inch.

EXAMPLE.—A magnetic circuit consists of 12 inches of cast steel of 8 square inches cross-section; 4 inches of cast iron of 22 square inches cross-section; 3 inches of sheet iron of 8 square inches cross-section; and two air-gaps each  $\frac{1}{16}$  inch long and of 12 square inches area. Required, the ampere-turns to produce a flux of 768,000 maxwells, which is to be uniform throughout the magnetic circuit.

The flux density in the steel is  $768,000 \div 8 = 96,000$  maxwells; the ampere-turns per inch of length, according to Sheldon's table, are 60.6, so that the 12 inches of steel will require 727.2 ampere-turns.

The density in the cast iron is  $768,000 \div 22 = 34,900$ ; the ampere-turns =  $4 \times 40 = 160$ .

The density in the sheet iron =  $768,000 \div 8 = 96,000$ ; ampere-turns per inch = 30; total ampere-turns for sheet iron = 90.

The air-gap density is  $768,000 \div 12 = 64,000$ ; ampere-turns per inch =  $0.3133B$ ; ampere-turns required for air-gap =  $0.3133 \times 64,000 \div 8 = 2506.4$ .

The entire circuit will require  $727.2 + 160 + 90 + 2506.4 = 3483.6$  ampere-turns, assuming uniform flux throughout.

In practice there is considerable "leakage" of magnetic lines of force; that is, many of the lines stray away from the useful path, there being no material opaque to magnetism and therefore no means of restricting it to a given path. The amount of leakage is proportional to the permeance of the leakage paths available between two points in a magnetic circuit which are at different magnetic potentials, such as opposite ends of a magnet coil. It is seldom practicable to predetermine with any approach to accuracy the magnetic leakage that will occur under given conditions unless one has profuse data obtained experimentally under similar conditions. In dynamo-electric machines the leakage coefficient varies from 1.3 to 2.

**Tractive or Lifting Force of a Magnet.**—The lifting power or “pull” exerted by an electro-magnet upon an armature in actual contact with its pole-faces is given by the formula

$$\frac{B^2 a}{72,134,000} = \text{Lbs.},$$

$a$  being the area of contact in square inches and  $B$  the magnetic density over this area. If the armature is very close to the pole-faces, this formula also applies with sufficient accuracy for all practical purposes, but a considerable air-gap renders it inapplicable. The accompanying table is convenient for approximating the dimensions of cores and pole-faces for tractive magnets.

**Dimensions of Lifting Magnets.**

Den- sity B.	Ampere-turns per inch of length.			Pull in lbs. per sq. in.	Den- sity B.	Ampere-turns per inch of length.			Pull in lbs. per sq. in.
	Air.	Cast Iron.	Cast Steel.			Air.	Cast Iron.	Cast Steel.	
10,000	3133	18	3.7	1.38	29,000	9,086	49	6.5	11.6

**Magnet Windings.**—Knowing the ampere-turns required to produce the desired excitation of a magnetic circuit, the winding may be approximately determined as follows:

For round cores under 1 inch in diameter make the depth or thickness of winding,  $t$ , equal to the core diameter; over 1 inch, let  $t$  = cube root of core diameter. For slab-shaped cores let the coil thickness be equal to the core thickness up to 1 inch, and to the square root of the core thickness above that.

The ampere-turns produced by any coil will be

$$A_t = \frac{Vd^2}{lk},$$

in which  $V$  = volts at the coil terminals,

$d^2$  = area of the wire in circular mils,

$l$  = mean length in inches per turn of wire,

$k$  = a coefficient depending on the temperature of the coil.

The mean length per turn of wire is

$$g + \pi t = l_m,$$

$g$  being the perimeter of the core. The size of wire required for a given excitation will be

$$d^2 = \frac{kA_t}{V}(g + \pi t).$$

At 140° Fahr.  $k=1$ . The table herewith gives the values of  $k$  at various other practical temperatures.

#### Values of $k$ in Magnet-coil Formula.

Temp.	$k$	Temp.	$k$	Temp.	$k$	Temp.	$k$
100	0.923	115	0.952	130	0.981	150	1.0195
105	0.933	120	0.962	135	0.99	155	1.029
110	0.942	125	0.971	145	1.01	160	1.0387

The rise above atmospheric temperature will be

$$\frac{V^2}{k_t R S} = \theta,$$

in which  $R$  = the resistance of the coil when hot,  $S$  = its radiating surface, and  $k_t$  is a variable coefficient (see p. 1032). The value of  $k_t$  will be about 0.008 for electro-magnets of ordinary size not enclosed or shielded in any way from the surrounding air.

For fuller treatment of the subject, see *American Electrician*, April and May, 1901, and January, 1904.

**Determining the Polarity of Electro-magnets.**—If a wire is wound around a magnet in a right-handed helix, the end at which the current flows into the helix is the south pole. If a wire is wound around an ordinary wood-screw, and the current flows around the helix in the direction from the head of the screw to the point, the head of the screw is the south pole. If a magnet is held so that the south pole is opposite the eye of the observer, the wire being wound as a right-handed helix around it, the current flows in a right-handed direction, with the hands of a clock.

**Determining the Direction of a Current.**—Place a wire carrying a current above and parallel to a pivoted magnetic needle. If the current be flowing along the wire from N. to S., it will cause the N.-seeking pole to turn to the eastward; if it be flowing from S. to N., the pole will turn to the westward. If the wire be below the needle, these motions will be reversed.

Maxwell's rule. The direction of the current and that of the resisting magnetic force are related to each other as are the rotation and the forward travel of an ordinary (right-handed) cork-screw.

**DYNAMO-ELECTRIC MACHINES.**

There are three classes of dynamo-electric machines, viz.:

1. Generators, for the conversion of mechanical into electrical energy.
2. Motors, for the conversion of electrical into mechanical energy.

Generators and motors are both subdivided into direct-current and alternating-current machines.

3. Transformers, for the conversion of one character or voltage of current into another, as direct into alternating or alternating into direct, or from one voltage into a higher or lower voltage.

**Kinds of Dynamo-electric Machines as regards Manner of Winding.**

1. *Separately-excited Dynamo.*—The field-magnet coils have no connection with the armature-coils, but receive their current from a separate machine or source.

2. *Series-wound Dynamo.*—The field winding and the external circuit are connected in series with the armature winding, so that the entire armature current must pass through the field-coils.

Since in a series-wound dynamo the armature-coils, the field, and the external circuit are in series, any increase in the resistance of the external circuit will decrease the electro-motive force from the decrease in the magnetizing currents. A decrease in the resistance of the external circuit will, in a like manner, increase the electro-motive force from the increase in the magnetizing current. The use of a regulator avoids these changes in the electro-motive force.

3. *Shunt-wound Dynamo.*—The field-magnet coils are placed in a shunt to the armature circuit, so that only a portion of the current generated passes through the field-magnet coils, but all the difference of potential of the armature acts at the terminals of the field-circuit.

In a shunt-wound dynamo an increase in the resistance of the external circuit increases the electro-motive force, and a decrease in the resistance of the external circuit decreases the electro-motive force. This is just the reverse of the series-wound dynamo.

In a shunt-wound dynamo a continuous balancing of the current occurs, the current dividing at the brushes between the field and the external circuit in the inverse proportion to the resistance of these circuits. If the resistance of the external circuit becomes greater, a proportionately greater current passes through the field-magnets, and so causes the electro-motive force to become greater. If, on the contrary, the resistance of the external circuit decreases, less current passes through the field, and the electro-motive force is proportionately decreased.

4. *Compound-wound Dynamo.*—The field-magnets are wound with two separate sets of coils, one of which is in series with the armature and the external circuit, and the other in shunt with the armature, or the external circuit.

*Motors.*—The above classification in regard to winding applies also to motors.

**Moving Force of a Dynamo-electric Machine.**—A wire through which a current passes has, when placed in a magnetic field, a tendency to move perpendicular to itself and at right angles to the lines of the field. The force producing this tendency is  $P = lBI$  dynes, in which  $l$  = length of the wire,  $I$  = the current in C.G.S. units, and  $B$  = the induction, or flux density, in the field in lines per square centimetre.

If the current  $I$  is taken in amperes,  $P = lBI \div 10 = lBI \cdot 10^{-1}$ .

If  $P_k$  is taken in kilogrammes,

$$P_k = lBI \div 9,810,000 = 10.1937 lBI \cdot 10^{-8} \text{ kilogrammes.}$$

**EXAMPLE.**—The mean strength of field,  $B$ , of a dynamo is 5000 C.G.S. lines; a current of 100 amperes flows through a wire; the force acts upon 10 centimetres of the wire =  $10.1937 \times 10 \times 100 \times 5000 \times 10^{-8} = .5097$  kilogrammes.

In the "English" or Kapp's system of measurement a total flow of 6000

C.G.S. lines is taken to equal one English line. Calling  $BE$  the induction in English, or Kapp's, lines per square inch, and  $B$  the induction in C. G. S. lines per square centimetre,  $BE = B \div 930.04$ ; and taking  $l'$  in inches and  $PP$  in pounds,  $PP = 531l'BE10^{-6}$  pounds.

**Torque of an Armature.**—The torque of an armature is the moment tending to turn it. In a generator it is the moment which must be applied to the armature to turn it in order to produce current. In a motor it is the turning moment which the armature gives to the pulley.

Let  $I$  = current in the armature in amperes,  $E$  = the electro-motive force in volts,  $T$  = the torque in pound-feet,  $\phi$  = the flux through the armature in maxwells,  $N$  = the number of conductors around the armature, and  $n$  = the number of revolutions per second. Then

$$\text{Watts} = IE = 2\pi nT \times 1.356.*$$

In any machine if the flux be constant,  $E$  is directly proportional to the speed and  $= \phi Nn \div 10^8$ ; whence

$$\frac{\phi NI}{10^8} = 2\pi T \times 1.356;$$

$$T = \frac{\phi NI}{10^8 \times 2\pi \times 1.356} = \frac{\phi NI}{8.52 \times 10^8} \text{ pound-feet.}$$

Let  $l$  = length of armature in inches,  $d$  = diameter of armature in inches,  $B$  = flux density in maxwells per square inch, and let  $m$  = the ratio of the conductors under the influence of the pole-pieces to the whole number of conductors on the armature. Then

$$\phi = \frac{\pi d}{2} \times l \times B \times m.$$

These formulæ apply to both generators and motors. They show that torque is independent of the speed and varies directly with the current and the flux. The total peripheral force is obtained by dividing the torque by the radius (in feet) of the armature, and the drag on each conductor is obtained by dividing the total peripheral force by the number of conductors under the influence of the pole-pieces at one time.

**EXAMPLE.**—Given an armature of length  $l = 20$  inches, diameter  $d = 12$  inches, number of conductors  $N = 120$ , of which 80 are under the influence of the pole-pieces at one time; let the flux density  $B = 30,000$  maxwells per sq. in. and the current  $I = 400$  amperes.

$$\phi = \frac{12\pi}{2} \times 20 \times 30,000 \times \frac{80}{120} = 7,540,000.$$

$$T = \frac{7,540,000 \times 120 \times 400}{8.52 \times 100,000,000} = 424.8 \text{ pound-feet.}$$

Total peripheral force =  $424.8 \div .5 = 849.6$  lbs.

Drag per conductor =  $849.6 \div 120 = 7.08$  lbs.

The work done in one revolution = torque  $\times$  circumference of a circle of 1 foot radius =  $424.8 \times 6.28 = 2670$  foot-pounds.

Let the revolutions per minute equal 500, then the horse-power

$$= \frac{2670 \times 500}{33000} = 40.5 \text{ H.P.}$$

**Electro-motive Force of the Armature Circuit.**—From the horse-power, calculated as above, together with the amperes, we can obtain the E.M. F., for  $IE = \text{H.P.} \times 746$ , whence E.M.F. or  $E = \text{H.P.} \times 746 \div I$ .

If H.P., as above, = 40.5, and  $I = 400$ ,  $E = \frac{40.5 \times 746}{400} = 75.5$  volts.

The E.M.F. may also be calculated by the following formulæ:

$I$  = Total current through armature;

$ea$  = E.M.F. in armature in volts;

$N$  = Number of active conductors counted all around armature;

$p$  = Number of pairs of poles ( $p = 1$  in a two-pole machine);

$n$  = Speed in revolutions per minute;

$\phi$  = Total flux in maxwells.

\* 1 ft.-lb. per second = 1.356 watts.

$$\text{Electro-motive force: } \left\{ \begin{array}{l} ea = \phi N \frac{n}{60} 10^{-8} \text{ for two-pole machines.} \\ ea = \frac{p\phi N n}{10^8} \frac{n}{60} \text{ for multipolar machines with series-wound armature.} \end{array} \right.$$

**Strength of the Magnetic Field.**—The fundamental equation for calculations relating to the magnetic circuit is

$$\text{Flux} = \frac{\text{Magneto-motive Force}}{\text{Reluctance}}.$$

Magneto-motive force is the magnetizing effect of an electric current. It varies directly as the number of turns in a coil, and as the current. It is numerically equal to  $1.257 \times \text{amperes} \times \text{turns}$ .

Reluctance is the resistance any material offers to the setting up in itself of magnetic lines. It varies directly as the length and inversely as the area of the cross-section of the core, taken at right angles to the direction of the magnetic lines, and inversely as the permeability of the material.

Let  $I$  = current in amperes,  $N$  = number of turns in the coil,  $A$  = area of the cross-section of the core in square centimetres,  $l$  = length of core in centimetres,  $\mu$  the permeability of the core, and  $\phi$  = flux in maxwells. Then

$$\phi = \frac{1.257NI}{(l \div A\mu)}.$$

In a dynamo-electric machine the reluctance will be made up of three separate quantities, viz.: the reluctance of the field magnet cores, the reluctance of the air spaces between the field magnet pole-pieces and the armature, and the reluctance of the armature. The total reluctance is the sum of the three. Let  $L_1, L_2, L_3$  be the length of the path of magnetic lines in the field magnet cores,\* in the air-gaps, and in the armature respectively; and let  $A_1, A_2, A_3$  be the areas of the cross-sections perpendicular to the path of the magnetic lines in the field magnet cores, the air-gaps, and the armature respectively. Let the permeability of the field magnet cores be  $\mu_1$ , and of the armature  $\mu_3$ . The permeability of the air-gaps is taken as unity. Then the total reluctance of the machine will be

$$\frac{L_1}{A_1 \mu_1} + \frac{L_2}{A_2} + \frac{L_3}{A_3 \mu_3}.$$

The formula for magnetic flux will now read

$$\phi = \frac{1.257NI}{(L_1 \div A_1\mu_1) + (L_2 \div A_2) + (L_3 \div A_3\mu_3)}.$$

The ampere turns necessary to create a given flux in a machine may be found by the formula

$$NI = \phi \frac{[(L_1 \div A_1 \mu_1) + (L_2 \div A_2) + (L_3 \div A_3 \mu_3)]}{1.257}.$$

But the total flux generated by the field coils is not available to produce current in the armature. There is a leakage between the field magnets, and this must be allowed for in calculations. The leakage coefficient varies from 1.3 to 2 in different machines. The meaning of the coefficient is that if a flux of say 100 maxwells per square cm. are desired in the field coils, it will be necessary to provide ampere turns for  $1.3 \times 100 = 130$  maxwells, if the leakage coefficient be 1.3.

Another method of calculating the ampere turns necessary to produce a given flux is to calculate the magneto-motive force required in each portion of the machine, separately, introducing the leakage coefficient in the calculation for the field magnets, and dividing the sum of the magnetive-motive forces by 1.257. An example of this last method is appended.

EXAMPLE.—Given a two-pole generator with a single magnetic circuit of the following dimensions, in centimetres and square centimetres:  $L_1 = 150, L_2 = \text{each } .5, L_3 = 25; A_1 = 1200, A_2 = 1400, A_3 = 1000$ ; leakage

\* The length of the path in the field magnet cores  $L_1$  includes that portion of the path which lies in the piece joining the cores of the various field magnets.

coefficient =  $\lambda = 1.32$ ; flux in armature = 10,000,000 maxwells. Required the ampere turns on field magnets. Let  $B =$  intensity of magnetic induction, or flux density, and  $H =$  intensity of the magnetic field.

$$\text{Armature: } B = \frac{\phi}{A_3} = \frac{10,000,000}{1000} = 10,000.$$

From the permeability table,  $\mu_3 = 2000$

$$M.M.F_3 = \phi \frac{L_3}{A_3 \mu_3} = \frac{10,000,000 \times 25}{1000 \times 2000} = 125.$$

Air-gaps:

$$M.M.F_2 = \frac{10,000,000 \times 2 \times .5}{1400} = 7150.$$

Field Cores:

$$B = \frac{\phi \times \lambda}{A_1} = \frac{10,000,000 \times 1.32}{1200} = 11,000; \mu = 1692.$$

$$M.M.F_1 = \frac{\phi \lambda L_1}{A_1 \mu_1} = \frac{10,000,000 \times 1.32 \times 150}{1200 \times 1692} = 975.$$

$$\text{Total } M.M.F. = 125 + 7150 + 975 = 8250.$$

$$\text{Ampere turns} = \frac{M.M.F.}{1.257} = \frac{8250}{1.257} = 6563.$$

In a machine having a double magnetic circuit, the calculation is slightly varied. The total flux is created by the two separate sets of windings, each set creating one half. The ampere turns are calculated for one set of windings. The flux,  $\phi$ , used in the calculation is taken as one half the total flux created. The areas of the air-gaps  $A_2$  and of the armature  $A_3$  are also taken as one half the actual area. Except for these changes, the calculation is made in the same manner as for the single magnetic circuit; the result is the ampere turns for one set of field windings.

In the ordinary type of multipolar machine there are as many magnetic circuits as there are poles. Each winding energizes part of two circuits. The calculation is made in the same manner as for a single magnetic circuit.

**Dynamo Design.**—In the design of a motor or generator the following data are usually given, being determined by local conditions. Class, viz., bipolar or multipolar, series, shunt or compound wound; size, in kilowatts; voltage; and current. The following is an outline of the method pursued in the complete design. (For complete method see Wiener's *Dynamo-electric Machines*.)

*Notation.*— $E =$  e.m.f. in external circuit in volts;  $E' =$  total e.m.f. generated in armature in volts;  $e =$  e.m.f. necessary to overcome internal resistances of machine;  $I =$  current in external circuit in amperes;  $I =$  current generated in armature in amperes;  $i =$  current in shunt field in amperes;  $H_1 =$  assumed flux density of field in maxwells per sq. inch;  $B =$  actual flux density in armature, maxwells per square inch.;  $L =$  length of armature in inches;  $D =$  diameter of armature in inches;  $l =$  length of active conductor (i.e., that on pole-facing surface of armature) in feet;  $d =$  diameter of armature conductor in mils;  $d^2 =$  area of armature conductor, circular mils;  $d' =$  diameter of insulated armature conductor in inches;  $N =$  number of conductors on armature;  $p =$  number of pairs of poles in field;  $C =$  number of bars on commutator;  $\phi =$  magnetic flux in armature in maxwells;  $\phi' =$  total magnetic flux;  $\lambda =$  leakage coefficient of magnetic circuit;  $V =$  mean velocity of armature conductors in feet per second;  $h =$  available depth of winding space on armature, inches (in a slotted armature  $h$  is the depth of slot);  $n_1 =$  number of wires stranded in parallel to make one armature conductor;  $n_2 =$  number of conductors per layer on armature;  $n_3 =$  number of layers of conductor on armature;  $k, m, b =$  variables and factors explained in the text.

A value is first assumed for  $H_1$ . This is governed by the size of the machine, the style of armature, the number of poles, and the material of the pole-pieces, magnet cores, and frame. For a smooth core armature in a 1 kw. bipolar machine, with cast-iron pole-pieces, it may be taken as 15,000 maxwells per sq. inch for cast-iron; for wrought iron or steel pole-pieces it may be taken at 22,000 maxwells. For a 300 kw. bipolar machine

it may be assumed at 30,000 maxwells with cast-iron pole-pieces, and at 45,000 with wrought-iron pole-pieces. In multipolar machines, the figures are from 5000 to 7000 higher in each case.

A formula for the length of active armature conductor is

$$l = \frac{E' \times p}{k \times \pi \times H_1}$$

The value of  $k$  is determined by multiplying  $10^{-8}$  by a factor ranging from 50 to 72, depending on the percentage of polar arc, i.e., the percentage of the armature subtended by the pole-pieces. If the percentage of polar arc is 50 the factor is 50, if the percentage is 100 the factor is 72.  $V$  varies from 35 in a 1 kw. machine to 50 in a 200 or 300 kw. machine with a drum armature. With ring armatures, in high speed machines,  $V$  varies from 65 in a 1 kw. machine to 75 in a 25 kw., 85 in a 300 kw, and 100 in a 5000 kw. machine. On low speed dynamos the figures are approximately one half the above.

$E' = (E + e)$ . In series machines, under 1 kw.,  $e$  is from 40 to 20 per cent of  $E$ ; in machines of from 1 to 25 kw., from 20 to 10 per cent; in 25 to 500 kw. machines, from 10 to 4 per cent; and in machines of over 500 kw. from 4 to 2.5 per cent of  $E$ . In shunt-wound machines  $e$  has approximately one half the value used in series machines; in compound-wound machines approximately three quarters the value used in series machines.

The diameter of the armature core is found by means of the assumed velocity and the given revolutions per minute,  $D = (12 \times 60V) \div (\text{r.p.m.} \times \pi)$ .

The area of the conductors on the armature depends on the amount of current to be carried.  $d^2 = 300 I' \div p$ .

In a series machine  $I' = I$ ; in shunt and compound machines  $I' = I + i$ . The current consumed in the shunt field varies with the size of the machine approximately as follows

kw. =	1	5	10	20	50	100	500	2000
$i =$	.08I	.06I	.05I	.04I	.03I	.0275I	.02I	.015I

In large machines it is better, in order to diminish the eddy currents, to make the armature conductors in the form of a cable, than to use single wires. If the conductor on the armature is a single wire the thickness of insulation varies from .012 to .020 inch, depending on the voltage. If the conductor is a cable, each strand is insulated with a thickness of from .005 to .01 inch and the entire cable is covered with insulation of thickness varying from .005 to .01 inch.

In a small machine with but a single layer of conductors on the armature  $L = l \div N$ .  $N = (1.885,000D \times h) \div d^2$ .

For drum armatures  $N = 2(n_2 \times n_3) \div n_1$ ;

for ring armatures  $N = (n_2 \times n_3) \div n_1$ .

A general formula given by Wiener for the length of armature is

$$L = \frac{12 \times n_1 \times l}{n_2 \times n_3}; \quad n_2 = \frac{D \times \pi}{d'}; \quad n_3 = \frac{h}{d'}$$

The minimum number of bars on the commutator is  $C_{\min} = E'p \div b$ . The value of  $b$  depends on the current as follows:

Amperes: over 100	100-50	50-20	20-10	10-5	5-2	2-1
$b$	10	10.5	11.5	12.5	15	20
					20	20.

The number which may be used, provided it does not fall below  $C_{\min}$  is

$$C = (n_2 \times n_3) \div n_1$$

For drum armatures the number of conductors attached to each commutator bar must be an even number. The quotient of  $C$ , obtained as above, by the largest even number which will give a result greater than  $C_{\min}$  is the proper number of commutator bars for drum armatures. For ring armatures it is the quotient of  $C$  by the largest number which will give a result greater than  $C_{\min}$ . In each case the divisor is the number of conductors which should be attached to each bar.

The flux through the armature is;

$$\phi = \frac{6 \times p \times E' \times 10^9}{N \times \text{r.p.m.}}$$

The flux density in the armature core is

$$B = \frac{\phi}{\pi \times D \times L \times m'}$$

where  $m$  is a factor depending on the percentage of polar arc. Assuming 100 per cent and 50 per cent as the limits of polar arc, the following are the respective values of  $m$  at those limits. In bipolar, smooth armature, machines  $m = 1.00$  and  $.70$ ; in bipolar, toothed armature machines  $m = 1.00$  and  $.55$ ; in smooth armature multipolar machines  $m = 1.00$  and  $.625$ , with from 4 to 12 poles;  $m = 1.00$  and  $.60$  with from 14 and 20 poles. With toothed armatures the figures are slightly lower.

The area of the field magnet cores depends on the flux to be generated.

$$\phi' = \phi \times \lambda.$$

A value for  $\lambda$  is assumed, which will vary with the size and type of machine. By means of this assumed value the principal dimensions of the magnetic circuit are calculated. The true value of  $\lambda$  is next calculated by means of the formula

$$\lambda = \frac{\text{Joint permeance of useful and stray paths}}{\text{Permeance of useful path}}$$

The permeance of a path is its magnetic conductance.

$$\text{Permeance} = (\text{Permeability} \times \text{Area}) \div \text{Length}.$$

The stray paths are those across the pole-pieces, across the magnet cores and between the pole-pieces and the yoke joining the magnet cores.

With the new value of  $\lambda$ ,  $\phi'$  is recalculated. If the true and assumed values of  $\lambda$  give a large difference in flux then the dimensions of the circuit must be changed and  $\lambda$  recalculated.

The areas of the various portions are found by dividing the total flux by the allowable flux density. The allowable flux densities in maxwells per square inch are as follows: Wrought iron, 90,000; cast steel, 85,000; cast iron, 40,000.

The various areas being known, the winding of the magnets is calculated as shown in the section on Strength of the Magnetic Field.

EXAMPLE.—Design a 200 K.W. bipolar, smooth drum armature, shunt dynamo, with wrought-iron pole-pieces, and cast iron magnet cores and yoke. Volts, 500; amperes, 400; R.P.M., 450.

Assume  $H_1 = 40,000$ ;  $V = 45$ ;  $e = .03E$ ;  $i = .025I$ ; percentage of polar arc = 85. Then  $E' = 515$ ;  $I' = 410$  and  $k = 68 \times 10^{-8}$ .

$$l = (515 \times 1 \times 100,000,000) \div (68 \times 45 \times 40,000) = 420.7 \text{ feet.}$$

$$D = (12 \times 60 \times 45) \div (450 \times 3.1416) = 22.91 \text{ inches.}$$

$d^2 = 300 \times 410 \div 1 = 123,000$ . In this size of machine it is desirable to use cables. Each conductor may be composed of three cables in parallel, each composed of seven wires. A No. 12 B. & S. gauge wire has an area of 6530 cir. mils, and  $7 \times 3 \times 6530 = 137,130$ , which is near enough to  $d^2$ .

To find  $d'$ . Number of strands on a diameter = 3. Insulation on each strand = .005; insulation of cable = .008; diameter No. 12 wire = .080808;  $d' = 3 \times (.0808 + 2 \times .005) + (2 \times .008) = .2884$  inch.

Assume  $h = .625$ ;  $n_1 = 3$ ;  $n_2 = 22.91 \times 3.1416 \div .2884 = 249$ ;  $n_3 = .625 \div .2884 = 2 + .$  Then  $L = (12 \times 3 \times 420.7) \div (2 \times 249) = 30.41$  inches.

$C_{\min} = 515 \times 1 \div 10 = 51.5$ ;  $C = (249 \times 2 \div 3) \div 4 = 41$  (too small);  $(249 \times 2 \div 3) \div 2 = 83$ .  $\therefore C = 83$ .

$$N = (2 \times 249) \times 2 \div 3 = 332.$$

$$\phi = 6 \times 1 \times 515 \times 1,000,000,000 \div 332 \times 450 = 20,683,000.$$

$$\text{Assume } m = .94; B = 20,683,000 \div (3.1416 \times 22.91 \times 30.41 \times .94) = 10777.$$

To calculate  $\lambda$  would require more space than can be spared here. Assume  $\lambda = 1.34$ .

$$\phi' = 1.34 \times 20,683,000 = 27,715,220.$$

$$\text{Area of magnet cores} = 27,715,220 \div 40000 = 692 \text{ sq. inches.}$$

$$\text{Diameter of magnet cores} = \sqrt{692 \times \frac{4}{\pi}} = 29.8 \text{ inches.}$$

**ALTERNATING CURRENTS.\***

The advantages of alternating over direct currents are: 1. Greater simplicity of dynamos and motors, no commutators being required; 2. The feasibility of obtaining high voltages, by means of static transformers, for cheapening the cost of transmission; 3. The facility of transforming from one voltage to another, either higher or lower, for different purposes.

A direct current is uniform in strength and direction, while an alternating current rapidly rises from zero to a maximum, falls to zero, reverses its direction, attains a maximum in the new direction, and again returns to zero. This series of changes can best be represented by a curve the abscissas of which represent time and the ordinates either current or electromotive force (e.m.f.). The curve usually chosen for this purpose is the sine curve, Fig. 172; the best forms of alternators give a curve that is a very close approximation to the sine curve, and all calculations and deductions of formulæ are based on it. The equation of the sine curve is  $y = \sin x$ , in which  $y$  is any ordinate, and  $x$  is the angle passed over by a moving radius vector.

After the flow of a direct current has been once established, the only opposition to the flow is the resistance offered by the conductor to the passage of current through it. This resistance of the conductor, in treating of alternating currents, is sometimes spoken of as the *ohmic resistance*. The word resistance, used alone, always means the ohmic resistance. In alternating currents, in addition to the resistance, several other quantities, which affect the flow of current, must be taken into consideration. These quantities are inductance, capacity, and skin effect. They are discussed under separate headings.

The current and the e.m.f. may be in phase with each other, that is, attain their maximum strength at the same instant, or they may not, depending on the character of the circuit. In a circuit containing only resistance, the current and e.m.f. are in phase; in a circuit containing inductance the e.m.f. attains its maximum value before the current, or leads the current. In a circuit containing capacity the current leads the e.m.f. If both capacity and inductance are present in a circuit, they will tend to neutralize each other.

**Maximum, Average, and Effective Values.**—The strength and the e.m.f. of an alternating current being constantly varied, the maximum value of either is attained only for an instant in each period. The maximum values are little used in calculations, except in deducing formulæ and for proportioning insulation, which must stand the maximum pressure.

The average value is obtained by averaging the ordinates of the sine curve representing the current, and is  $2 \div \pi$  or 0.637 of the maximum value.

The value of greatest importance is the effective, or "square root of the mean square," value. It is obtained by taking the square root of the mean of the squares of the ordinates of the sine curve. The effective value is the value shown on alternating-current measuring instruments. The product of the square of the effective value of the current and the resistance of circuit is the heat lost in the circuit.

The comparison of the maximum, average, and effective values is as follows:

$$E_{\text{Effec.}} = E_{\text{Max.}} \times 0.707; \quad E_{\text{Aver.}} = E_{\text{Max.}} \times 0.637; \quad E_{\text{Max.}} = 1.41 \times E_{\text{Effec.}}$$

**Frequency.**—The time required for an alternating current to pass through one complete cycle, as from one maximum point to the next ( $a$  and  $b$ , Fig. 172) is termed the period. The number of periods in a second is termed the frequency of the current. Since the current changes its direction twice in each period, the number of reversals or alternations is double the frequency. A current of 120 alternations per second has a period of  $1/60$

\* Only a very brief treatment of the subject of alternating currents can be given in this book. The following works are recommended as valuable for reference: *Alternating Currents and Alternating Current Machinery*, by D. C. and J. P. Jackson; *Standard Polyphase Apparatus and Systems*, by M. A. Oudin; *Polyphase Electric Currents*, by S. P. Thompson; *Electric Lighting*, by F. B. Crocker, 2 vols.; *Electric Power Transmission*, by Louis Bell; *Alternating Currents*, by Bedell and Crehore; *Alternating-current Phenomena*, by Chas. P. Steinmetz. The two last named are highly mathematical.

and a frequency of 60. The frequency of a current is equal to one half the number of poles on the generator, multiplied by the number of revolutions per second. Frequency is denoted by the letter  $f$ .

The frequencies most generally used in the United States are 25, 40, 60, 125, and 133 cycles per second. The Standardization Report of the A. I. E. E. recommends the adoption of three frequencies, viz. 25, 60, and 120.

With the higher frequencies both transformers and conductors will be less costly in a circuit of a given resistance, but the capacity and inductance effects in each will be increased, and these tend to increase the cost. With high frequencies it also becomes difficult to operate alternators in parallel.

A low-frequency current cannot be used on lighting circuits, as the lights will flicker when the frequency drops below a certain figure. For arc lights the frequency should not be less than 40. For incandescent lamps it should not be less than 25. If the circuit is to supply both power and light, a frequency of 60 is usually desirable. For power transmission to long distances a low frequency, say 25, is considered desirable, in order to lessen the capacity effects. If the alternating current is to be converted into direct current for lighting purpose, a low frequency may be used as the frequency will then have no effect on the lights.

**Inductance.**—A current flowing through a conductor produces a magnetic flux around the conductor. If the current be changed in strength or direction, the flux is also changed, producing in the conductor an e.m.f. whose direction is opposed to that of the current in the conductor. This counter e.m.f. is the *counter e.m.f. of inductance*. It is proportional to the rate of change of current, provided that the permeability of the medium around the conductor remains constant. The unit of inductance is the *henry* symbol  $L$ . A circuit has an inductance of one henry if a uniform variation of current at the rate of one ampere per second produces a counter e.m.f. of one volt.

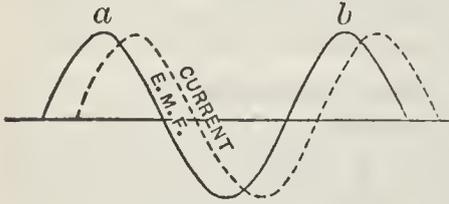

FIG. 172.

The effect of inductance on the circuit is to cause the current to lag behind the e.m.f. as shown in Fig. 172, in which abscissas represent time, and ordinates represent e.m.f. and current strengths respectively.

**Capacity.**—Any insulated conductor has the power of holding a quantity of static electricity. This power is termed the *capacity* of the body. The capacity of a circuit is measured by the quantity of electricity in it when at unit potential. It may be increased by means of a condenser. A condenser consists of two parallel conductors, insulated from each other by a non-conductor. The conductors are usually in sheet form.

The unit of capacity is a *farad*, symbol  $C$ . A condenser has a capacity of one farad when one coulomb of electricity contained in it produces a difference of potential of one volt. The farad is too large a unit to be conveniently used in practice, and the micro-farad is used instead.

The effect of capacity on a circuit is to cause the e.m.f. to lag behind the current. Both inductance and capacity may be measured with a Wheatstone bridge by substituting for a standard resistance a standard of inductance or a standard of capacity.

**Power Factor.**—In direct-current work the power, measured in watts, is the product of the volts and amperes in the circuit. In alternating-current work this is only true when the current and e.m.f. are in phase. If the current either lags or leads, the values shown on the volt and ammeters will not be true simultaneous values. Referring to Fig. 172, it will be seen that the product of the ordinates of current and e.m.f. at any particular instant will not be equal to the product of the effective values which are shown on the instruments. The power in the circuit at any instant is the product of the simultaneous values of current and e.m.f., and the volts and amperes shown on the recording instruments must be multiplied together and their product multiplied by a power factor before the true watts are obtained. This power factor, which is the ratio of the volt-amperes to the watts, is also the cosine of the angle of lag or lead of the current. Thus

$$P = I \times E \times \text{power factor} = I \times E \times \cos \theta$$

where  $\theta$  is the angle of lag or lead of the current.

A watt-meter, however, gives the true power in a circuit directly. The method of obtaining the angle of lag is shown below, in the section on Impedance Polygons.

**Reactance, Impedance, Admittance.**—In addition to the ohmic resistance of a circuit there are also resistances due to inductance, capacity, and skin effect. The virtual resistance due to inductance and capacity is termed the reactance of the circuit. If inductance only be present in the circuit, the reactance will vary directly as the inductance. If capacity only be present, the reactance will vary inversely as the capacity.

$$\text{Inductive reactance} = 2\pi fL.$$

$$\text{Condensive reactance} = \frac{1}{2\pi fC}.$$

The total apparent resistance of the circuit, due to both the ohmic resistance and the reactance, is termed the impedance, and is equal to the square root of the sum of the squares of the resistance and the reactance.

$$\text{Impedance} = Z = \sqrt{R^2 + (2\pi fL)^2} \text{ when inductance is present in the circuit.}$$

$$\text{Impedance} = Z = \sqrt{R^2 + \left(\frac{1}{2\pi fC}\right)^2} \text{ when capacity is present in the circuit.}$$

Admittance is the reciprocal of impedance,  $= 1 \div Z$ .

If both inductance and capacity are present in the circuit, the reactance of one tends to balance that of the other; the total reactance is the algebraic sum of the two reactances; thus,

$$\text{Total reactance} = X = 2\pi fL - \frac{1}{2\pi fC}; \quad Z = \sqrt{R^2 + \left(2\pi fL - \frac{1}{2\pi fC}\right)^2}.$$

In all cases the tangent of the angle of lag or lead is the reactance divided by the resistance. In the last case

$$\tan \theta = \frac{2\pi fL - \frac{1}{2\pi fC}}{R}.$$

**Skin Effect.**—Alternating currents tend to have a greater density at the surface than at the axis of a conductor. The effect of this is to make the virtual resistance of a wire greater than its true ohmic resistance. With low frequencies and small wires the skin effect is small, but it becomes quite important with high frequencies and large wires.

The following table, condensed from one in Foster's "Electrical Engineers' Pocket-book," shows the increase in resistance due to skin effect.

**Skin-effect Factors for Conductors carrying Alternating Currents.**

Diameter and B. & S. Gauge.	Frequencies.				
	25	40	60	100	130
0	.....	.....	1.001	1.005	1.008
00	.....	1.001	1.002	1.006	1.010
000	.....	1.002	1.005	1.010	1.017
0000	1.001	1.005	1.006	1.015	1.027
$\frac{1}{2}$ "	1.002	1.006	1.008	1.022	1.039
$\frac{3}{4}$ "	1.007	1.016	1.040	1.100	1.156
1	1.020	1.052	1.111	1.263	1.397
$1\frac{1}{4}$ "	1.053	1.118	1.239	1.506	1.694
$1\frac{1}{2}$ "	1.098	1.223	1.420	1.765	1.983
2"	1.265	1.531	1.826	2.290	2.560

For virtual resistance, multiply ohmic resistance by factor from this table.

**Ohm's Law applied to Alternating-current Circuits.**—To apply Ohm's law to alternating-current circuits a slight change is necessary in the expression of the law. Impedance is substituted for resistance. The law should read

$$I = \frac{E}{\sqrt{R^2 + X^2}} = \frac{E}{Z}$$

**Impedance Polygons.**—1. *Series Circuits.*—The impedance of a circuit can be determined graphically as follows. Suppose a circuit to contain a resistance  $R$  and an inductance  $L$ , and to carry a current  $I$  of frequency  $f$ . In Fig. 173 draw the line  $ab$  proportional to  $R$ , and representing the direction of current. At  $b$  erect  $bc$  perpendicular to  $ab$  and proportional to  $2\pi fL$ . Join  $a$  and  $c$ . The line  $ac$  represents the impedance of the circuit. The angle  $\theta$  between  $ab$  and  $ac$  is the angle of lag of the current behind the e.m.f., and the power factor of the circuit is cosine  $\theta$ . The e.m.f. of the circuit is  $E = IZ$ .

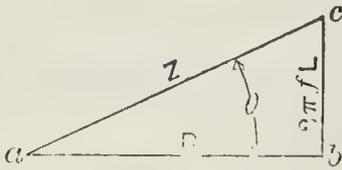

FIG. 173.

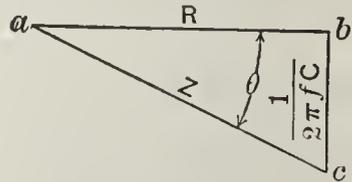

FIG. 174.

If the above circuit contained, instead of the inductance  $L$ , a capacity  $C$ , then would the polygon be drawn as in Fig. 174. The line  $bc$  would be proportional to  $\frac{1}{2\pi fC}$  and would be drawn in a direction opposite to that of  $bc$  in Fig. 173. The impedance would again be  $Z$ , the e.m.f. would be  $Z \times I$ , but the current would lead the e.m.f. by the angle  $\theta$ .

Suppose the circuit to contain resistance, inductance, and capacity. The lines of the impedance polygon would then be laid off as in Fig. 175. The impedance of the circuit would be represented by  $ad$ , and the angle of lag by  $\theta$ . If the capacity of the circuit had been such that  $cd$  was less than  $bc$ , then would the e.m.f. have led the current.

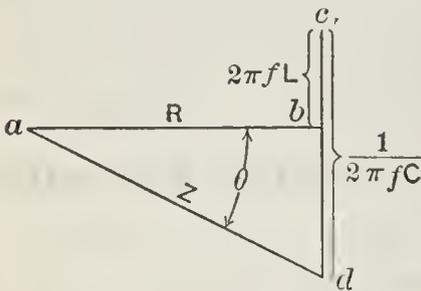

FIG. 175.

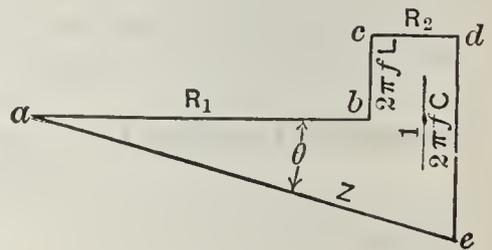

FIG. 176.

If between the inductance and capacity in the circuit in the previous examples there be interposed another resistance, the impedance polygon will take the form of Fig. 176. The lines representing either resistances, inductances, or capacities in the circuit follow each other in all cases as do the resistances, inductances, and capacities in the circuit, each line having its appropriate direction and magnitude.

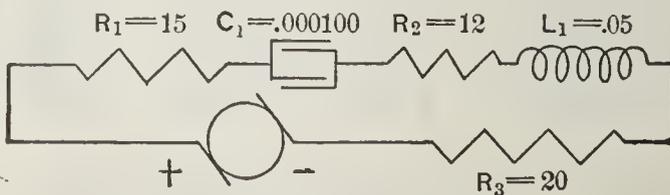

FIG. 177.

**EXAMPLE.**—A circuit (Fig. 177) contains a resistance,  $R_1$ , of 15 ohms, a capacity,  $C_1$ , of 100 microfarads (.000100 farad), a resistance,  $R_2$ , of 12 ohms, an inductance  $L_1$ , of .05 henrys, and a resistance  $R_3$ , of 20 ohms. Find the impedance and electromotive force when a current of 2 amperes is sent through the circuit, and the current when an e.m.f. of 120 volts is impressed on the circuit frequency being taken as 60. Also find the angle of lag, the power factor, and the power in the circuit when 120 volts are impressed.

The resistance is represented in Fig. 178 by the horizontal line  $ab$ , 15 units long. The capacity is represented by the line  $bc$ , drawn downwards from  $b$ , and whose length is

$$\frac{1}{2\pi f C_1} = \frac{1}{2 \times 3.1416 \times 60 \times .0001} = 26.55.$$

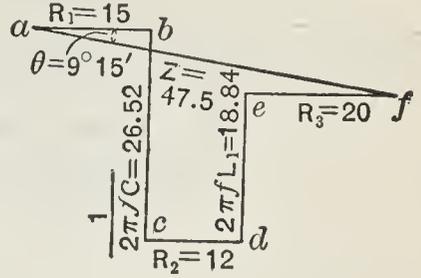

FIG. 178.

From the point  $c$  a horizontal line  $cd$ , 12 units long, is drawn to represent  $R_2$ . From the point  $d$  the line  $de$  is drawn vertically upwards to represent the inductance  $L_1$ . Its length is

$$2\pi f L_1 = 2 \times 3.1416 \times 60 \times .05 = 18.85.$$

From the point  $e$  a horizontal line  $ef$ , 20 units long, is drawn to represent  $R_3$ . The line joining  $a$  and  $f$  will represent the impedance of the circuit in ohms. The angle  $\theta$ , between  $ab$  and  $af$ , is the angle of lag of the e.m.f. behind the current. The impedance in this case is 47.5 ohms, and the angle of lag is  $9^\circ 15'$ .

The e.m.f. when a current of 2 amperes is sent through is

$$IZ = E = 2 \times 47.5 = 95 \text{ volts.}$$

If an e.m.f. of 120 volts be impressed on the circuit, the current flowing through will be

$$I = \frac{120}{Z} = \frac{120}{47.5} = 2.53 \text{ amperes.}$$

The power factor =  $\cos \theta = \cos 9^\circ 15' = .987$ .

The power in the circuit at 120 volts is

$$I \times E \times \cos \theta = 2.53 \times 120 \times .987 = 299.6 \text{ watts.}$$

**2. Parallel Circuits.**—If two circuits be arranged in parallel, the current flowing in each circuit will be inversely proportional to the impedance of that circuit. The e.m.f. of each circuit is the e.m.f. across the terminals at either end of the main circuit, where the various branches separate.

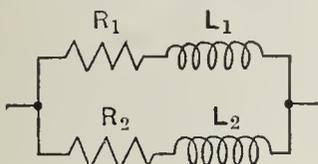

FIG. 179.

Consider a circuit, Fig. 179, consisting of two branches. The first branch contains a resistance  $R_1$  and an inductance  $L_1$  in series with it. The second branch contains a resistance  $R_2$  in series with an inductance  $L_2$ . The impedance of the circuit may be determined by treating each of the two

branches as a separate series circuit, and drawing the impedance polygon for each branch on that assumption. Having found the impedance the current flowing in either branch will be the reciprocal of the impedance multiplied by the e.m.f. across the terminals. The current in the entire circuit is the geometrical sum of the current in the two branches.

The admittance of the equivalent simple circuit may be obtained by drawing a parallelogram, two of whose adjoining sides are made parallel to the impedance lines of each branch and equal to the two admittances respectively.

The diagonal of the parallelogram will represent the admittance of the equivalent simple circuit. The admittance multiplied by the e.m.f. gives the total current in the circuit.

**EXAMPLE.**—Given the circuit in Fig. 180, consisting of two branches. Branch 1 consists of a resistance  $R_1 = 12$  ohms, an inductance  $L_1 = .05$  henry, a resistance  $R_2 = 4$  ohms, and a capacity  $C_1 = 120$  microfarads (.00012 farad). Branch 2 consists of an inductance  $L_2 = .015$  henry, a resistance  $R_3 = 10$  ohms, and an inductance  $L_3 = .03$  henry. An e.m.f. of 100 volts is impressed on the circuit at a frequency of 60. Find the ad-

mittance of the entire circuit, the current, the power factor, and the power in the circuit. Construct the impedance polygons for the two branches

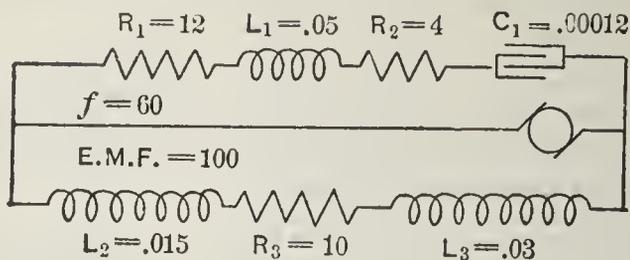

FIG. 180.

separately as shown in Fig. 181, *a* and *b*. The impedance in branch 1 is 16.4 ohms, and the current is  $\frac{1}{16.4} \times 100 = 6.19$  amperes. The angle of

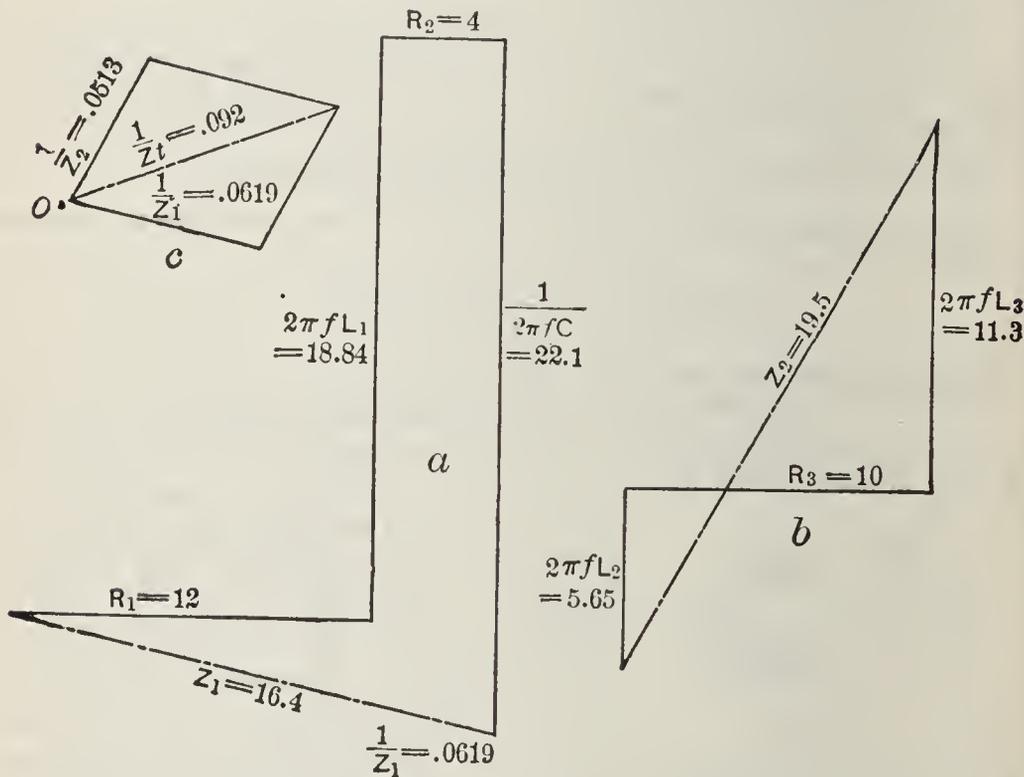

FIG. 181.

lead of the current is  $12^\circ 45'$ . The impedance in branch 2 is 19.5 ohms and the current is  $\frac{1}{19.5} \times 100 = 5.13$  amperes. The angle of lag of the current is  $61^\circ$ .

The current in the entire circuit is found by taking the admittances of the two branches, and drawing them from the point *o*, in Fig. 181 *c*, parallel to the impedance lines in their respective polygons. The diagonal from *o* is the admittance of the entire circuit, and in this case is equal to 0.092. The current in the circuit is  $.092 \times 100 = 9.2$  amperes. The power factor is 0.944 and the power in the circuit is  $100 \times .944 \times 9.2 = 868.48$  watts.

**Self-inductance of Lines and Circuits.**—The following formulæ and table, taken from Crocker's "Electric Lighting," give a method of calculating the self-inductance of two parallel aerial wires forming part of the same circuit and composed of copper, or other non-magnetic material.

$$L \text{ per foot} = \left(15.24 + 140.3 \log \frac{2A}{d}\right) 10^{-9},$$

$$L \text{ per mile} = \left(80.5 + 740 \log \frac{2A}{d}\right) 10^{-6},$$

in which  $L$  is the inductance in henrys of each wire,  $A$  is the interaxial distance between the two wires, and  $d$  is the diameter of each, both in inches. If the circuit is of iron wire, the formulæ become

$$L \text{ per foot} = \left(2286 + 140.3 \log \frac{2A}{d}\right) 10^{-9},$$

$$L \text{ per mile} = \left(12070 + 740 \log \frac{2A}{d}\right) 10^{-6}.$$

INDUCTANCE, IN MILLIHENRYS PER MILE, FOR EACH OF TWO PARALLEL COPPER WIRES.

Interaxial Distance, Ins.	American Wire Gauge Number											
	0000	000	00	0	1	2	3	4	6	8	10	12
3	0.907	0.944	0.982	1.019	1.056	1.094	1.131	1.168	1.243	1.317	1.392	1.467

**Capacity of Conductors.**—All conductors are included in three classes, viz.: 1. Insulated conductors with metallic protection; 2. Single aerial conductor with earth return; 3. Metallic circuit consisting of two parallel aerial wires. The capacity of the lines may be calculated by means of the following formulæ taken from Crocker's "Electric Lighting":

$$\text{Class 1. } C \text{ per foot} = \frac{7361k 10^{-15}}{\log (D \div d)}, \quad C \text{ per mile} = \frac{38.83k 10^{-9}}{\log (D \div d)}.$$

$$\text{Class 2. } C \text{ per foot} = \frac{7361 \times 10^{-15}}{\log (4h \div d)}, \quad C \text{ per mile} = \frac{38.83 \times 10^{-9}}{\log (4h \div d)}.$$

$$\text{Class 3. } \begin{cases} C \text{ per foot of each wire} = \frac{3681 \times 10^{-15}}{\log (2A \div d)}, \\ C \text{ per mile of each wire} = \frac{19.42 \times 10^{-9}}{\log (2A \div d)}. \end{cases}$$

In which  $C$  is the capacity in farads,  $D$  the internal diameter of the metallic covering,  $d$  the diameter of the conductor,  $h$  the height of the conductor above the ground, and  $A$  the interaxial distance between two parallel wires, all in inches;  $k$  is a dielectric constant which for air is equal to 1 and for pure rubber is equal to 2.5. The formulæ in cases 2 and 3 assume the wires to be bare. If they are insulated,  $k$  must be introduced in the numerator and given a value slightly greater than 1.

**Single-phase and Polyphase Currents.**—A single-phase current is a simple alternating current carried on a single pair of wires, and is generated on a machine having a single armature winding. It is represented by a single sine curve.

Polyphase currents are known as two-phase, three-phase, six-phase, or any other number, and are represented by a corresponding number of sine curves. The most commonly used systems are the two-phase and three-phase.

1. *Two-phase Currents.*—In a two-phase system there are two single-phase alternating currents bearing a definite time relation to each other and represented by two sine curves (Fig. 182).

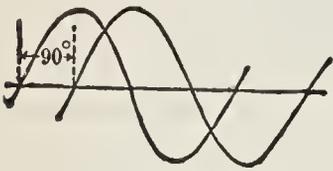

FIG. 182.

The two separate currents may be generated by the same or by separate machines. If by separate machines, the armatures of the two should be positively coupled together. Two-phase currents are usually generated by a machine with two armature windings, each winding terminating in two collector rings. The two windings are so related that the two currents will be 90° apart. For this reason two-phase currents are also called "quarter-phase" currents.

Two-phase currents may be distributed on either three or four wires. The three-wire system of distribution is shown in Fig. 183. One of the return wires is dispensed with, connection being made across to the other as shown. The common return wire should be made 1.41 times the area of either of the other two wires, these two being equal in size.

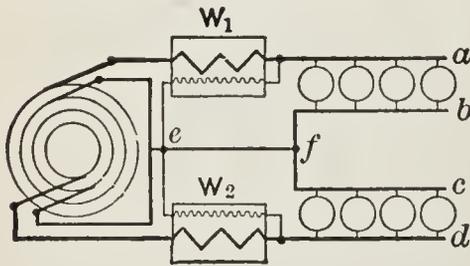

FIG. 183.

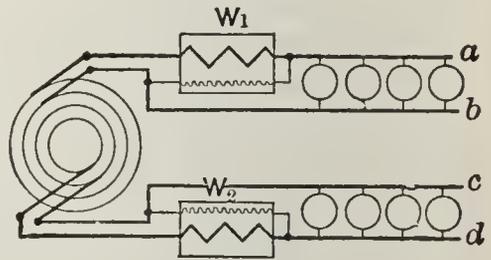

FIG. 184.

The four-wire system of distribution is shown in Fig. 184. The two phases are entirely independent, and for lighting purposes may be operated as two single-phase circuits.

2. *Three-phase Currents.*—Three-phase currents consist of three alternating currents, differing in phase by 120°, and represented by three sine curves, as in Fig. 185. They may be distributed by three or six wires. If distributed by the six-wire system, it is analogous to the four-wire, two-phase system, and is equivalent to three single-phase circuits. In the three-wire system of distribution the circuits may be connected in two different ways, known respectively as the Y or star connection, and the Δ (delta) or mesh connection.

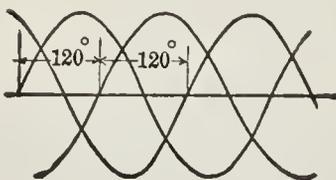

FIG. 185.

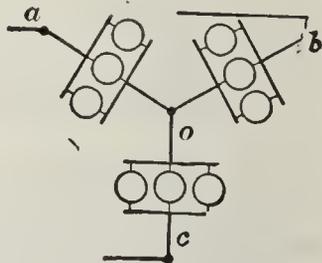

FIG. 186.

The  $Y$  connection is shown in Fig. 186. The three circuits are joined at the point  $o$ , known as the neutral point, and the three wires carrying the current are connected at the points  $a$ ,  $b$ , and  $c$ , respectively. If the three circuits  $ao$ ,  $bo$ , and  $co$  are composed of lights, they must be equally loaded or the lights will fluctuate. If the three circuits are perfectly balanced, the lights will remain steady. In this form of connection each wire may be considered as the return wire for the other two. If the three circuits are unbalanced, a return wire may be run from the neutral point  $o$  to the neutral point of the armature winding on the generator. The system will then be four-wire, and will work properly with unbalanced circuits.

The  $\Delta$  connection is shown in Fig. 187. Each of the three circuits  $ab$ ,  $ac$ ,  $bc$ , receives the current due to a separate coil in the armature winding. This form of connection will work properly even if the circuits are unbalanced; and if the circuit contains lamps, they will not fluctuate when the circuit changes from a balanced to an unbalanced condition, or *vice versa*.

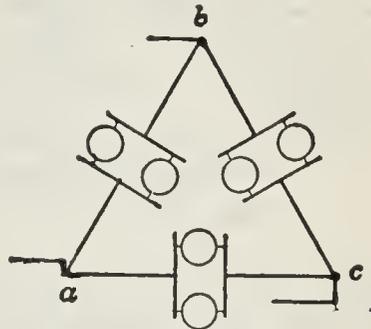

FIG. 187.

**Measurement of Power in Polyphase Circuits.**—1. *Two-phase Circuits.*—The power of two-phase currents distributed by four wires may be measured by two wattmeters introduced into the circuit as shown in Fig. 184. The sum of the readings of the two instruments is the total power. If but one wattmeter is available, it should be introduced first in one circuit, and then in the other. If the current or e.m.f. does not vary during the operation, the result will be correct. If the circuits are perfectly balanced, twice the reading of one wattmeter will be the total power.

The power of two-phase currents distributed by three wires may be measured by two wattmeters as shown in Fig. 183. The sum of the two readings is the total power. If but one wattmeter is available, the coarse-wire coil should be connected in series with the wire  $ef$  and one extremity of the pressure-coil should be connected to some point on  $ef$ . The other end should be connected first to the wire  $a$  and then to the wire  $d$ , a reading being taken in each position of the wire. The sum of the readings gives the power in the circuits.

2. *Three-phase Currents.*—The power in a three-phase circuit may be measured by three wattmeters, connected as in Fig. 188 if the system is  $Y$ -connected, and as in Fig. 189 if the system is  $\Delta$ -connected. The sum

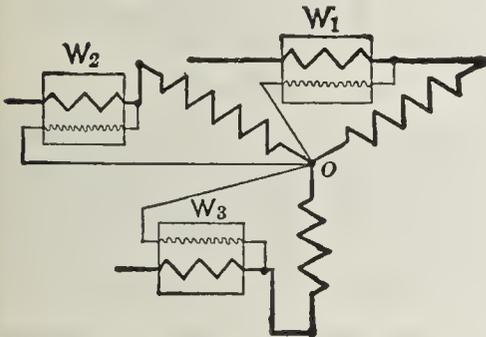

FIG. 188.

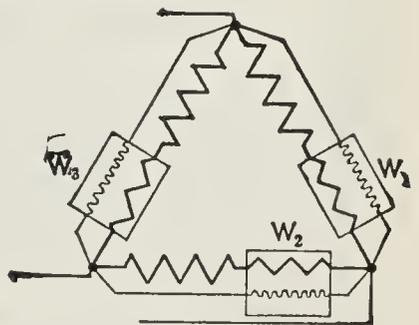

FIG. 189.

of the wattmeter readings gives the power in the system. If the circuits are perfectly balanced, three times the reading of one wattmeter is the total power.

The power in a  $\Delta$ -connected system may be measured by two wattmeters, as shown in Fig. 190. If the power factor of the system is greater than 0.50, the arithmetical sum of the readings is the power in the circuit. If the power factor is less than 0.50, the arithmetical difference of the readings is the power. Whether the power factor is greater or less than 0.50 may be discovered by interchanging the wattmeters without disturbing the

relative connection of their coarse- and fine-wire coils. If the deflections of the needles are reversed, the difference of the readings is the power. If the needles are deflected in the same direction as at first, the sum of the readings is the power.

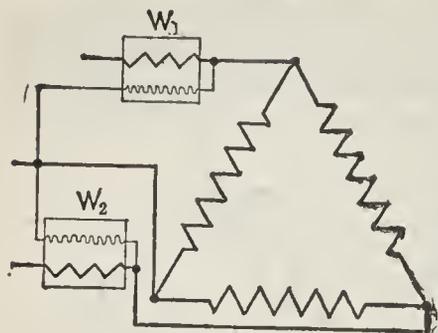

FIG. 190.

of their own current around the fields through a rectifying device which changes the current to pulsating direct current. In all large machines the armature is stationary and the field-magnets revolve.

### TRANSFORMERS, CONVERTERS, ETC.

**Transformers.**—A transformer consists essentially of two coils of wire, one coarse and one fine, wound upon an iron core. The function of a transformer is to convert electrical energy from one potential to another. If the transformer causes a change from high to low voltage, it is known as a “step-down” transformer; if from low to high voltage, it is known as a “step-up” transformer.

The relation of the primary and secondary voltages depends on the number of turns in the two coils. Transformers may also be used to change current of one phase to current of another phase. The windings and the arrangement of the transformers must be adapted to each particular case. In Fig. 191 an arrangement is shown whereby two-phase currents may be converted into three-phase. Two transformers are required, one having its primary and secondary coils in the relation of 100 to 100, and the other having its primary and secondary in the relation of 100 to 86. The secondary of the 100-to-100 transformer is tapped at its middle point and joined to one terminal of the other secondary. Between any pair of the three remaining terminals of the secondaries there will exist a difference of potential of 50.

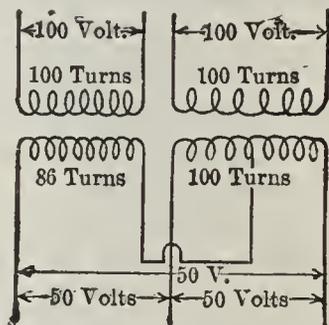

FIG. 191.

There are two sources of loss in the transformer, viz., the copper loss and the iron loss. The copper loss is proportional to the square of the current, being the  $I^2R$  loss due to heat. If  $I_1, R_1$ , be the current and resistance respectively of the primary, and  $I_2, R_2$ , the current and resistance respectively of the secondary, then the total copper loss is  $W_c = I_1^2R_1 + I_2^2R_2$  and the percentage of copper loss is  $\frac{I_1^2R_1 + I_2^2R_2}{W_p}$ , where  $W_p$  is the energy delivered

to the primary. The iron loss is constant at all loads, and is due to hysteresis and eddy currents.

Transformers are sometimes cooled by means of forced air or water currents or by immersing them in oil, which tends to equalize the temperature in all parts of the transformer.

**Efficiency of Transformers.**—The efficiency of a transformer is the ratio of the output in watts at the secondary terminals to the input at the primary terminals. At full load the output is equal to the input less the iron and copper losses. The full-load efficiency of transformers is usually very high, being from 92 per cent. to 98 per cent. As the copper loss varies as the square of the load, the efficiency of a transformer varies considerably at different loads. Transformers on lighting circuits usually operate at full

load but a very small part of the day, though they use some current all the time to supply the iron losses. For transformers operated only a part of the time the "all-day" efficiency is more important than the full-load efficiency. It is computed by comparing the watt-hours output to the watt-hours input.

The all-day efficiency of a 10-K.W. transformer, whose copper and iron losses at full load are each 1.5 per cent, and which operates 3 hours at full load, 2 hours at half load, and 19 hours at no load, is computed as follows:

Iron loss, all loads =  $10 \times .015 = .15$  K.W.  
 Copper loss, full load =  $10 \times .015 = .15$  K.W.  
 Copper loss,  $\frac{1}{2}$  load =  $.15 \times (\frac{1}{2})^2 = .0375$  K.W.  
 Iron loss K.W. hours =  $.15 \times 24 = 3.6$ .  
 Copper loss, full load, K.W. hours =  $.15 \times 3 = .45$ .  
 Copper loss,  $\frac{1}{2}$  load, K.W. hours =  $.0375 \times 2 = .075$ .  
 Output. K.W. hours =  $\{ (10 \times 3) + (5 \times 2) \} = 40$ .  
 Input, K.W. hours =  $40 + 3.6 + .45 + .075 = 44.125$ .  
 All-day efficiency =  $40 \div 44.125 = .907$ .

The transformers heretofore discussed are constant-potential transformers and operate at a constant voltage with a variable current. For the operation of lamps in series a constant-current transformer is required. There are a number of types of this transformer. That manufactured by the General Electric Co. operates by causing the primary and secondary coils to approach or to separate on any change in the current.

**Converters, etc.**—In addition to static transformers, various machines are used for the purpose of changing the voltage of direct currents or the voltage, phase or frequency of alternating currents, and also for changing alternating currents to direct or vice versa. These machines are all rotary and are known as rotary converters, motor-dynamos, and dynamotors.

A rotary converter consists of a field excited by the machine itself, and an armature which is provided with both collector rings and a commutator. It receives direct current and changes it to alternating, working as a direct-current motor, or it changes alternating to direct current, working as a synchronous motor.

A motor-dynamo consists of a motor and a dynamo mounted on the same base and coupled together by a shaft.

A dynamotor has one field and two armature windings on the same core. One winding performs the functions of a motor armature, and the other those of a dynamo armature.

A booster is a machine inserted in series in a direct-current circuit to change its voltage. It may be driven either by an electric motor or otherwise.

## ALTERNATING-CURRENT MOTORS.

**Synchronous Motors.**—Any alternator may be used as a motor, provided it be brought into synchronism with the generator supplying the current to it. The operation of the alternating-current motor and generator is similar to the operation of two generators in parallel. It is necessary to supply direct current to the field. The field circuit is left open until the machine is in phase with the generator. If the motor has the same number of poles as the generator, it will run at the same speed; if a different number the speed will be that of the generator multiplied by the ratio of the number of poles of the motor to that of the generator. Single-phase, synchronous motors are not self-starting. Polyphase motors may be made self-starting but it is better to bring the machines to speed by independent means before supplying the current. The machines may be started by a small induction motor, the load on the synchronous motor being thrown off, or the field may be excited by a small direct-current generator belted to the motor, and this generator may be used as a motor to start the machine, current to run it being taken from a storage battery. If the field of a synchronous motor be properly regulated to the load, the motor will exercise no inductive effect on the line, and the power factor will be 1. If the load varies the current in the motor will either lead or lag behind the e.m.f. and will vary the power factor. If the motor be overloaded so that there is a diminution of speed the motor will fall out of step with the generator and stop.

Synchronous motors are often put on the same circuit with induction motors. The synchronous motor in this case may, by increasing the field excitation, be made to cause the current to lead, while the induction motor

will cause it to lag. The two effects will thus tend to balance each other and cause the power factor of the circuit to approach 1.

Synchronous motors are best used for large units of power at high voltages, where the load is constant and the speed invariable. They are unsatisfactory where the required speed is variable and the load changes. Two great disadvantages of the synchronous motor are its inability to start under load, and the necessity of direct-current excitation.

**Induction Motors.**—The distinguishing feature of an induction motor is the rotating magnetic field. It is thus explained: In Fig 192 let *ab, cd*

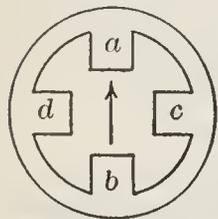

FIG. 192.

be two pairs of poles of a motor, *a* and *b* being wound from one leg or pair of wires of a two-phase alternating circuit, and *c* and *d* from the other leg, the two phases being  $90^\circ$  apart. At the instant when *a* and *b* are receiving maximum current, so as to make *a* a north pole and *b* a south pole, *c* and *d* are demagnetized, and a needle placed between the poles would stand as shown in the cut. During the progress of the cycle of the current the magnetic flux at *a* decreases and that at *c* increases causing the point of resultant maximum intensity to shift, and the needle to move clockwise toward *c*. A complete rotation of the resultant point is performed during each cycle of the current. An armature placed within the ring is caused to rotate simply by the shifting of the magnetic field without the use of a collector ring. The words "rotating magnetic field" refer to an area of magnetic intensity and must be distinguished from the words "revolving field" which refer to the portion of the machine constituting the field-magnet.

The field or "primary" of an Induction motor is that portion of the machine to which current is supplied from the outside circuit.

The armature or "secondary" is that portion of the machine in which currents are induced by the rotating magnetic field. Either the primary or the secondary may revolve. In the more modern machines the secondary revolves. The revolving part is called the "rotor," the stationary part the "stator." The rotor may be either of the ring or the drum type, the drum type being more common. A common type of armature is the "squirrel-cage." It consists of a number of copper bars placed on the armature-core and insulated from it. A copper ring at each end connects the bars. The field windings are always so arranged that more than one pair of poles are produced. This is necessary in order to bring the speed down to a practical limit. If but one pair of poles were produced, with a frequency of 60, the revolutions per minute would be 3600.

The revolving part of an induction motor does not rotate as fast as the field, except at no load. When loaded, a slip is necessary, in order that the lines of force may cut the conductors in the rotor and induce currents therein. The current required for starting an induction motor of the squirrel-cage type under full load is 7 or 8 times as great as the current for running at full-load. A type of induction motor known as 'Form L,' built by the General Electric Co., will start with the full load current, provided the starting torque is not greater than the torque when running at full load.

Induction motors should be run as near their normal primary e.m.f. as possible, as the output and torque are directly proportional to the square of the primary pressure. A machine which will carry an overload of 50 per cent at normal e.m.f. will hardly carry its full load at 80 per cent of the normal e.m.f.

An induction motor exercises its greatest torque when standing still, and its least when running in synchronism with the rotating field. If it be overloaded it will slow down until the induced currents in the armature are sufficient to carry the load.

## ALTERNATING-CURRENT CIRCUITS.

**Calculation of Alternating-current Circuits.**—The following formulæ and tables are issued by the General Electric Co. They afford a convenient method of calculating the sizes of conductors for, and determining the losses in, alternating-current circuits. They apply to circuits in which the conductors are spaced 18 inches apart, but a slight increase or decrease in this distance does not alter the figures appreciably. If the conductors are less than 18 inches apart, the loss of voltage is decreased and vice versa.

- Let  $W$  = total power delivered in watts;  
 $D$  = distance of transmission (one way) in feet;  
 $P^*$  = per cent loss of *delivered* power ( $W$ );  
 $E$  = voltage between main conductors at consumer's end of circuit;  
 $K$  = a constant; for continuous current = 2160;  
 $T$  = a variable depending on the system and nature of the load; for continuous current = 1;  
 $M$  = a variable, depending on the size of wire and the frequency; for continuous current = 1;  
 $A$  = a factor; for continuous current = 6.04.

$$\text{Area of conductor, circular mils} = \frac{D \times W \times K}{P \times E^2};$$

$$\text{Current in main conductors} = \frac{W \times T}{E};$$

$$\text{Volts lost in lines} = \frac{P \times E \times M}{100};$$

$$\text{Pounds copper} = \frac{D^2 \times W \times K \times A}{P \times E^2 \times 1,000,000}.$$

The following tables give values for the various constants.

Per cent of Power Factor.	Value of $K$ .				Value of $T$ .				Value of $A$ .
	100	95	85	80	100	95	85	80	
System:									
Single-phase . . . . .	2160	2400	3000	3380	1.00	1.65	1.17	1.25	6.04
Two-phase 4-wire . . . . .	1080	1200	1500	1690	.50	.53	.59	.62	12.08
Three-phase, 3-wire . . . . .	1080	1200	1500	1690	.58	.61	.68	.72	9.06

20	360	150	24	810	125	28	1800	107	40	6000	75

From 360 to 810 kw. the machines are wound for 370 volts; from 72 to 810 kw. for 480 volts; from 810 to 6000 kw. for 2300 volts; and from 360 to 6000 kw. for 6600 and 13,200 volts.

60 CYCLES.

Poles.	Kw.	R.P.M.	Poles.	Kw.	R.P.M.	Poles.	Kw.	R.P.M.	Poles.	Kw.	R.P.M.
26	72	276	56	360	128.5	60	810	120	80	1800	90
28	108	257	64	360	112.5	72	810	100	72	2700	100
32	160	225	48	540	150	60	1200	120	84	2700	86
36	240	200	56	540	128.5	72	1200	100			
48	240	150	63	540	103	64	1800	112.5			
48	360	150	52	810	138.5	72	1800	100			

From 72 to 360 kw. the machines are wound for 240 volts; from 72 to 1200 kw. for 480 volts; from 72 to 2700 kw. for 2300 volts; from 540 to 2700 kw. some machines are wound for 6600 volts.

The kw. ratings in the above table are based on the load that may be carried without a rise in temperature of any part exceeding 40° C. above the surrounding atmosphere when running continuously with non-inductive full load. An overload of 25%, non-inductive, may be carried for two hours without heating more than 55° C. When full non inductive load is thrown off, with fixed normal excitation, the voltage will rise approximately 8%. When full load with 80% power factor is thrown off, with fixed excitation, the rise will be approximately 2%.

A rating one-sixth less is given all machines for a rise of temperature not exceeding 35°C. above surrounding atmosphere.

For other kinds of wood than white oak multiply the figures in the table by a figure selected from those given below (which represent the safe stress per square inch on beams of different kinds of wood according to the building laws of the cities named) and divide by 1000.

	Hemlock.	Spruce.	White pine.	Oak.	Yellow Pine.
New York.....	800	900	900	1100	1100*
Boston. ....	.....	750	750	1000†	1250
Chicago.....	.....	.....	900	1080	1440

\* Georgia pine.

† White oak.

**MATHEMATICS.**

**Formula for Interpolation.**

$$a_n = a_1 + (n - 1)d_1 + \frac{(n - 1)(n - 2)}{1.2} d_2 + \frac{(n - 1)(n - 2)(n - 3)}{1.2.3} d_3 + \dots$$

$a_1$  = the first term of the series;  $n$ , number of the required term;  $a_n$ , the required term;  $d_1, d_2, d_3$ , first terms of successive orders of differences between  $a_1, a_2, a_3, a_4$ , successive terms.

EXAMPLE.—Required the log of 40.7, logs of 40, 41, 42, 43 being given as below.

Terms $a_1, a_2, a_3, a_4$ :	1.6021	1.6128	1.6232	1.6335
1st differences:		.0107	.0104	.0103
2d " "		— .0003	— .0001	
3d " "			+ .0002	

For log. 40  $n = 1$ ; log 41  $n = 2$ ; log 40.7  $n = 1.7, n - 1 = 0.7, n - 2 = - 0.3, n - 3 = - .1.3$ .

$$a_n = 1.6021 + 0.7(.0107) + \frac{(0.7)(- 0.3)(- .0003)}{2} + \frac{(0.7)(- 0.3)(- 1.3)(.0002)}{6}$$

$$= 1.6021 + .00749 + .000031 + .000009 = 1.6096 +.$$

**Maxima and Minima without the Calculus.**—In the equation  $y = a + bx + cx^2$ , in which  $a, b$ , and  $c$  are constants, either positive or negative, if  $c$  be positive  $y$  is a minimum when  $x = - b \div 2c$ ; if  $c$  be negative  $y$  is a maximum when  $x = - b \div 2c$ . In the equation  $y = a + bx + c/x, y$  is a minimum when  $bx = c/x$ .

APPLICATION.—The cost of electrical transmission is made up (1) of fixed charges, such as superintendence, repairs, cost of poles, etc., which may be represented by  $a$ ; (2) of interest on cost of the wire, which varies with the sectional area, and may be represented by  $bx$ ; and (3) of cost of the energy wasted in transnission, which varies inversely with the area of the wire, or  $c/x$ . The total cost,  $y = a + bx + c/x$ , is a minimum when item 2 = item 3, or  $bx = c/x$ .

**RIVETED JOINTS.**

**Pressure Required to Drive Hot Rivets.**—R. D. Wood & Co., Philadelphia, give the following table (1897):

POWER TO DRIVE RIVETS HOT.

Size.	Girder-work.	Tank-work.	Boiler-work.	Size.	Girder-work.	Tank-work.	Boiler-work.
in.	tons.	tons.	tons.	in.	tons.	tons.	tons.
$\frac{1}{2}$	9	15	20	$\frac{1}{8}$	38	60	75
$\frac{5}{8}$	12	18	25	$\frac{1}{4}$	45	70	100
$\frac{3}{4}$	15	22	33	$\frac{1}{2}$	60	85	125
$\frac{7}{8}$	22	30	45	$\frac{3}{4}$	75	100	150
1	30	45	60				

The above is based on the rivet passing through only two thicknesses of plate which together exceed the diameter of the rivet but little, if any.

As the plate thickness increases the power required increases approximately in proportion to the square root of the increase of thickness. Thus, if the total thickness of plate is four times the diameter of the rivet, we should require twice the power given above in order to thoroughly fill the rivet-holes and do good work. Double the thickness of plate would increase the necessary power about 40%.

It takes about four or five times as much power to drive rivets cold as to drive them hot. Thus, a machine that will drive  $\frac{3}{4}$ -in. rivets hot will usually drive  $\frac{3}{8}$ -in. rivets cold (steel). Baldwin Locomotive Works drive  $\frac{1}{2}$ -in. soft-iron rivets cold with 15 tons.

**HEATING AND VENTILATION.****Table of Capacities for Hot-blast or Plenum Heating with Fans or Blowers.**

(Computed by F. R. Still, American Blower Co., Detroit, Mich.)

Size of Blower-housing.	Diam. of Fan-wheel.	Revolutions per minute.	H.P. required to drive Fan.	Cu. Ft. of Air Delivered per minute by Fan through Heater.	Cu. Ft. of Air per hour.	Heat Units required per hour to raise air from 0° to 120°.	Velocity of Air through Coils in ft. per minute.	Free Area between Pipes in sq. ft.	Heat Units given off per sq. ft. surface per hour.	Sq. Ft. Heating Surface required.

200	12,420	7560	10	5	252	3780	108	63,200	70.25	60,000

Temperature of fresh air, 0°; of air from coils, 120°; of steam, 227°. Pressure of steam, 5 lbs.

Peripheral velocity of fan-tips, 4000 ft.; number of pipes deep in coil, 24; depth of coil, 60 inches; area of coils approximately twice free area.

**WATER-WHEELS.****Water-power Plants Operating under High Pressures.—**

The following notes are contributed by the Pelton Water Wheel Co.:

The Consolidated Virginia & Col. Mining Co., Virginia, Nev., has a 3-ft. steel-disk Pelton wheel operating under 2100 ft. fall, equal to 911 lbs. per sq. in. It runs at a peripheral velocity of 10,804 ft. per minute and has a capacity of over 100 H.P. The rigidity with which water under such a high pressure as this leaves the nozzle is shown in the fact that it is impossible to cut the

stream with an axe, however heavy the blow, as it will rebound just as it would from a steel rod travelling at a high rate of speed.

The London Hydraulic Power Co. has a large number of Pelton wheels from 12 to 18 in. diameter running under pressure of about 1000 lbs. per sq. in. from a system of pressure-mains. The 18-in. wheels weighing 30 lbs. have a capacity of over 20 H.P. (See Blaine's "Hydraulic Machinery.")

Hydraulic Power-hoist of Milwaukee Mining Co., Idaho.—One cage travels up as the other descends; the maximum load of 5500 lbs. at a speed of 400 ft. per min. is carried by one of a pair of Pelton wheels (one for each cage). Wheels are started and stopped by opening and closing a small hydraulic valve at the engineer's stand which operates the larger valves by hydraulic pressure. An air-chamber takes up the shock that would otherwise occur on the pipe line under the pressure due to 850 ft. fall.

The Mannesmann Cycle Tube Works, North Adams, Mass., are using four Pelton wheels, having a fly-wheel rim, under a pump pressure of 600 lbs. per sq. in. These wheels are direct-connected to the rolls through which the ingots are passed for drawing out seamless tubing.

The Alaska Gold Mining Co., Douglass Island, Alaska, has a 22-ft. Pelton wheel on the shaft of a Riedler duplex compressor. It is used as a fly-wheel as well, weighing 25,000 lbs.—and develops 500 H.P. at 75 revolutions. A valve connected to the pressure-chamber starts and stops the wheel automatically, thus maintaining the pressure in the air-receiver.

At Pachuca in Mexico five Pelton wheels having a capacity of 600 H.P. each under 800 ft. head are driving an electric transmission plant. These wheels weigh less than 500 lbs. each, showing over a horse-power per pound of metal.

**Formulae for Calculating the Power of Jet Water-wheels,** such as the Pelton (F. K. Blue).—*HP* = horse-power delivered;  $\delta$  = 62.36 lbs. per cu. ft.; *E* = efficiency of turbine; *q* = quantity of water, cubic feet per minute; *h* = feet effective head; *d* = inches diameter of jet; *p* = pounds per square inch effective head; *c* = coefficient of discharge from nozzle, which may be ordinarily taken at 0.9.

$$HP = \frac{\delta E q h}{33000} = .00189 E q h = .00436 E q p = .00496 E c d^2 \sqrt{h^3} = .0174 E c d^2 \sqrt{p^3}.$$

$$q = 529.2 \frac{HP}{E h} = 229 \frac{HP}{E p} = 2.62 c d^2 \sqrt{h} = 3.99 c d^2 \sqrt{p}.$$

$$d^2 = 201.6 \frac{HP}{E c \sqrt{h^3}} = 57.4 \frac{HP}{E c \sqrt{p^3}} = .381 \frac{q}{c \sqrt{h}} = .25 \frac{q}{c \sqrt{p}}.$$

**GAS FUEL.**

**Average Volumetric Composition, Energy, etc., of Various Gases.** (Contributed by R. D. Wood & Co., Philadelphia, 1898.)

\* The real energy of bituminous producer-gas when used hot is far in excess of that indicated by the above table, on account of the hydrocarbons, which do not show, as they are condensed in the act of collecting the gas for analysis. In actual practice there is found to be about 50% more effective energy in bituminous gas than in anthracite gas when used hot enough to prevent condensation in the flues.

† Cubic feet of air required to burn 1 lb. of coal with blast.

**STEAM-BOILERS.**

**Steam-boiler Construction.** (Extract from the Rules and Specifications of the Hartford Steam Boiler Inspection & Insurance Co., 1898.)  
Cylindrical boiler shells of fire box steel, and tube-heads of best flange steel. Limits of tensile strength between 55,000 and 62,000 lbs. per sq. in.

Iron rivets in steel plates, 38,000 lbs. shearing strength per sq. in. in single shear, and 85% more, or 70,300 lbs., in double shear.

Each shell-plate must bear a test-coupon which shall be sheared off and tested. Each coupon must fulfil the above requirements as to tensile strength, but must have a contraction of area of not less than 56% and an elongation of 25% in a length of 8 in. It must also stand bending 180° when cold, when red hot, and after being heated red hot and quenched in cold water, without fracture on outside of bent portion.

Crow-foot braces are required for boiler-heads without welds, and if of iron limit the strain to 7500 lbs. per sq. in., and stay-bolts must not be subjected to a greater strain than 6000 lbs. per sq. in.

The thickness of double butt-straps  $\frac{8}{10}$  the thickness of plates. In lap-joints the distance between the rows of rivets is  $\frac{2}{3}$  the pitch. In double-riveted lap-joints of plates up to  $\frac{1}{2}$  in. thick the efficiency is 70% and in triple-riveted lap-joints 75% of the solid plate.

In triple-riveted double-strapped butt-seams for plates from  $\frac{1}{4}$  in. to  $\frac{1}{2}$  in. thick, the efficiency ranges from 88% to 86% of the solid plate.

In high-pressure boilers the holes are required to be drilled in place; that is, all holes may be punched  $\frac{1}{4}$  in. less than full size, then the courses are rolled up, tube-heads and joint-covering plates bolted to courses, with all holes together perfectly fair. Then the rivet-holes are drilled to full size, and when completed the plates are taken apart and the burr removed.

The rule for the bursting-pressure of cylindrical boiler-shells is the following: Multiply the ultimate tensile strength of the weakest plate in the shell by its thickness in inches and by the efficiency of the joint, and divide result by the semi-diameter of shell; the quotient is the bursting-pressure per square inch. This pressure divided by the factor 5 gives the allowable working pressure.

**BOILER FEEDING.**

**Gravity Boiler-feeders.**—If a closed tank be placed above the level of the water in a boiler and the tank be filled or partly filled with water, then on shutting off the supply to the tank, admitting steam from the boiler to the upper part of the tank, so as to equalize the steam-pressure in the boiler and in the tank, and opening a valve in a pipe leading from the tank to the boiler the water will run into the boiler. An apparatus of this kind may be made to work with practically perfect efficiency as a boiler-feeder, as an injector does, when the feed-supply is at ordinary atmospheric temperature, since after the tank is emptied of water and the valves in the pipes connecting it with the boiler are closed the condensation of the steam remaining in the tank will create a vacuum which will lift a fresh supply of water into the tank. The only loss of energy in the cycle of operations is the radiation from the tank and pipes, which may be made very small by proper covering.

When the feed-water supply is hot, such as the return water from a heating system, the gravity apparatus may be made to work by having two receivers, one at a low level, which receives the returns or other feed-supply, and the other at a point above the boilers. A partial vacuum being created in the upper tank, steam-pressure is applied above the water in the lower tank by which it is elevated into the upper. The operation of such a machine may be made automatic by suitable arrangement of valves. (See circular of the Scott Boiler Feeder, made by the Q. & C. Co., Chicago.)

**FEED-WATER HEATERS.**

**Capacity of Feed-water Heaters.**—The following extract from a letter by W. R. Billings, treasurer of the Taunton Locomotive Manufacturing Co., builders of the Wainwright feed-water heater, to *Engineering Record*, February, 1898, is of interest in showing the relation of the heating surface of a heater to the work done by it:

“Closed feed-water heaters are seldom provided with sufficient surface to raise the feed temperature to more than 200°. The rate of heat trans-

mission may be measured by the number of British thermal units which pass through a square foot of tubular surface in one hour for each degree of difference in temperature between the water and the steam. The difficulties which attend experiments in this direction can only be appreciated by those who have attempted to make such experiments. Certain results have been reached, however, which point to what appears to be a reasonable conclusion. One set of experiments made quite recently gave certain results which may be set forth in the table herewith.

Difference between final tempera- tures of water and steam	$\left\{ \begin{array}{l} 5^{\circ} \text{ F.} \dots\dots\dots 67 \text{ B.T.U.} \\ 6^{\circ} \text{ " } \dots\dots\dots 79 \text{ " } \\ 8^{\circ} \text{ " } \dots\dots\dots 89 \text{ " } \\ 11^{\circ} \text{ " } \dots\dots\dots 114 \text{ " } \\ 15^{\circ} \text{ " } \dots\dots\dots 129 \text{ " } \\ 18^{\circ} \text{ " } \dots\dots\dots 139 \text{ " } \end{array} \right.$	$\left. \begin{array}{l} \text{Transmitted in one} \\ \text{hour by each sq. ft.} \\ \text{of surface for each} \\ \text{degree of average} \\ \text{difference in temper-} \\ \text{atures.} \end{array} \right\}$
---	---	---

“In other words, when the water was brought to within 5° of the temperature of the heating medium, heat was transmitted through the tubes at the rate of 67 B.T.U. per square foot for each degree of difference in temperature in one hour. When the amount of water flowing through the heater was so largely increased as to make it impossible to get the water any nearer than within 18° of the temperature of the steam, the heat was transmitted at the rate of 139 B.T.U. per sq. ft. of surface for each degree of difference in temperature in one hour. Note here that even with the rate of transmission as low as 67 B.T.U. the water was still 5° from the temperature of the steam. At what rate would the heat have been transmitted if the water could have been brought to within 2° of the temperature of the steam, or to 21° when the steam is at 212° ?

“For commercial purposes feed-water heaters are given a H.P. rating which allows about one-third of a square foot of surface per H.P.—a boiler H.P. being 30 lbs. of water per hour. If the figures given in the table above are accepted as substantially correct, a heater which is to raise 3000 lbs. of water per hour from 60° to 207°, using exhaust steam at 212° as a heating medium, should have nearly 84 sq. ft. of heating surface—that is, a 100 H.P. feed-water heater which is to maintain a constant temperature of not less than 207°, with water flowing through it at the rate of 3000 lbs. per hour, should have nearly a square foot of surface per H.P. That feed-water heaters do not carry this amount of heating surface is well known.”

**THE STEAM-ENGINE.**

**Current Practice in Engine Proportions, 1897** (Compare pages 792 to 817.)—A paper with this title by Prof. John H. Barr, in Trans. A. S. M. E., xviii, 737, gives the results of an examination of the proportions of parts of a great number of single-cylinder engines made by different builders. The engines classed as low speed (L. S.) are Corliss or other long-stroke engines usually making not more than 100 or 125 revs. per min. Those classed as high speed (H. S.) have a stroke generally of 1 to 1½ diameters and a speed of 200 to 300 revs. per min. The results are expressed in formulas of rational form with empirical coefficients, and are here abridged as follows :

*Thickness of Shell, L. S. only.*— $t = CD + B$ ;  $D$  = diam. of piston in in.;  $B = 0.3$  in.;  $C$  varies from 0.04 to 0.06, mean = 0.05.

*Flanges and Cylinder-heads.*—1 to 1.5 times thickness of shell, mean 1.2.

*Cylinder-head Studs.*—No studs less than ¾ in. nor greater than 1½ in. diam. Least number, 8, for 10 in diam. Average number =  $0.7D$ . Average diam. =  $D/40 + ½$  in.

*Ports and Pipes.*— $a$  = area of port (or pipe) in sq. in.;  $A$  = area of piston, sq. in.;  $V$  = mean piston-speed, ft. per min.;  $a = AV/C$ , in which  $C$  = mean velocity of steam through the port or pipe in ft. per min.

*Ports, H. S.* (same ports for steam as for exhaust).— $C = 4500$  to  $6500$ , mean  $5500$ . For ordinary piston-speed of 600 ft. per min.  $a = KA$ ;  $K = .09$  to  $.13$ , mean  $.11$ .

*Steam-ports, L. S.*— $C = 5000$  to  $9000$ , mean  $6800$ ;  $K = .08$  to  $.10$ , mean  $.09$ .

*Exhaust-ports, L. S.*— $C = 4000$  to  $7000$ , mean  $5500$ ;  $K = .10$  to  $.125$ , mean  $.11$ .

*Steam-pipes, H. S.*— $C = 5800$  to  $7000$ , mean  $6500$ . If  $d$  = diam. of pipe and  $D$  = diam. of piston,  $d = .29D$  to  $.32D$ , mean  $.30D$ .

*Steam-pipes, L. S.*— $C = 5000$  to  $8000$ , mean  $6000$ ;  $d = .27$  to  $.35D$ , mean  $.32D$ .

*Exhaust-pipes, H. S.*— $C = 2500$  to  $5500$ , mean  $4400$ ;  $d = .33$  to  $.50D$ , mean  $.37D$ .

*Exhaust-pipes, L. S.*— $C = 2800$  to  $4700$ , mean  $3800$ ;  $d = .35$  to  $.45D$ , mean  $.40D$ .

*Face of Pistons.*— $F$  = face;  $D$  = diameter.  $F = CD$ . H. S.:  $C = .30$  to  $.60$  mean  $.46$ . L. S.:  $C = .25$  to  $.45$ , mean  $.32$ .

*Piston-rods.*— $d$  = diam. of rod;  $D$  = diam. of piston;  $L$  = stroke, in.;  $d = C\sqrt{DL}$ . H. S.:  $C = .12$  to  $.175$ , mean  $.145$ . L. S.:  $C = .10$  to  $.13$ , mean  $.11$ .

*Connecting-rods.*—H. S. (generally 6 cranks long, rectangular section):  $b$  = breadth;  $h$  = height of section;  $L_1$  = length of connecting-rod;  $D$  = diam. of piston;  $b = C\sqrt{DL_1}$ ;  $C = .045$  to  $.07$ , mean  $.057$ ;  $h = Kb$ ;  $K = 2.2$  to  $4$ , mean  $2.7$ . L. S. (generally 5 cranks long, circular sections only):  $C = .082$  to  $.105$ , mean  $.092$ .

*Cross-head Slides.*—Maximum pressure in lbs. per sq. in. of shoe, due to the vertical component of the force on the connecting-rod. H. S.:  $10.5$  to  $38$ , mean  $27$ . L. S.:  $29$  to  $38$ , mean  $40$ .

*Cross-head Pins.*— $l$  = length;  $d$  = diam.; projected area =  $a = dl = CA$ ;  $A$  = area of piston;  $l = Kd$ . H. S.:  $C = .06$  to  $.11$ , mean  $.08$ ;  $K = 1$  to  $2$ , mean  $1.25$ . L. S.:  $C = .054$  to  $.10$ , mean  $.07$ ;  $K = 1$  to  $1.5$ , mean  $1.3$ .

*Crank-pin.*— $HP$  = horse-power of engine;  $L$  = length of stroke;  $l$  = length of pin;  $l = C \times HP/L + B$ ;  $d$  = diam. of pin;  $A$  = area of piston;  $dl = KA$ . H. S.:  $C = .13$  to  $.46$ , mean  $.30$ ;  $B = 2.5$  in.;  $K = .17$  to  $.44$ , mean  $.24$ . L. S.:  $C = .4$  to  $.8$ , mean  $.6$ ;  $B = 2$  in.;  $K = .065$  to  $.115$ , mean  $.09$ .

*Crank-shaft Main Journal.*— $d = C\sqrt[3]{HP \div N}$ ;  $d$  = diam.;  $l$  = length;  $N$  = revs. per min.; projected area =  $MA$ ;  $A$  = area of piston. H. S.:  $C = 6.5$  to  $8.5$ , mean  $7.3$ ;  $K = 2$  to  $3$ , mean  $2.2$ ;  $M = .37$  to  $.70$ , mean  $.46$ . L. S.:  $C = 6$  to  $8$ , mean  $6.8$ ;  $K = 1.7$  to  $2.1$ , mean  $1.9$ ;  $M = .46$  to  $.64$ , mean  $.56$ .

*Piston-speed.*—H. S.:  $530$  to  $660$ , mean  $600$ ; L. S.:  $500$  to  $850$ , mean  $600$ .

*Weight of Reciprocating Parts* (piston, piston-rod, cross-head, and one-half of connecting-rod).— $W = CD^2 \div LN^2$ ;  $D$  = diam. of piston;  $L$  = length of stroke, in.;  $N$  = revs per min. H. S. only:  $C = 1,200,000$  to  $2,300,000$ , mean  $1,860,000$ .

*Belt-surface per I.H.P.*— $S = CHP + B$ ;  $S$  = product of width of belt in feet by velocity of belt in ft. per min. H. S.:  $C = 21$  to  $40$  mean  $28$ ;  $B = 1800$ . L. S.:  $S = C \times HP$ ;  $C = 30$  to  $42$ , mean  $= 35$ .

*Fly-wheel* (H. S. only).—Weight of rim in lbs.:  $W = C \times HP \div D_1^2 N^2$ ;  $D_1$  = diam. of wheel in in.;  $C = 65 \times 10^{10}$  to  $2 \times 10^{12}$  mean  $= 12 \times 10^{11}$ , or  $1,200,000,000,000$ .

*Weight of Engine per I.H.P. in lbs., including fly-wheel.*— $W = C \times H.P.$  H. S.:  $C = 100$  to  $135$ , mean  $115$ . L. S.:  $C = 135$  to  $240$ , mean  $175$ .

**Work of Steam-turbines.** (See p. 791.)—A 300-H.P. De Laval steam-turbine at the 12th Street station of the Edison Electric Illuminating Co. in New York City in April, 1896, showed on a test a steam-consumption of 19.275 lbs. of steam per electrical H.P. per hour, equivalent to 17.348 lbs. per brake H.P., assuming an efficiency of the dynamo of 90%. The steam-pressure was 145 lbs. gauge and the vacuum 26 in. It drove two 100-K.W. dynamos. The turbine-disk was 29.5 in. diameter and its speed 9000 revs. per min. The dynamos were geared down to 750 revs. The total equipment, including turbine, gearing, and dynamos, occupied a space 13 ft. 3 in. long, 6 ft. 5 in. wide, and 4 ft. 3 in. high.

The "Turbinia," a torpedo-boat 100 ft. long, 9 ft. beam, and 44½ tons displacement, was driven at 31 knots per hour by a Parsons steam-turbine in 1897, developing a calculated I.H.P. of 1576 and a thrust H.P. of 946, the steam-pressure at the engine being 130 lbs. and at the boilers 200 lbs. The vacuum was 13½ lbs. The revolutions averaged 2100 per minute. The calculated steam-consumption was 15.86 lbs. per I.H.P. per hour. On another trial the "Turbinia" developed a speed of 32¾ knots.

**Relative Cost of Different Sizes of Steam-engines.**

(From catalogue of the Buckeye Engine Co., Part III.)

Horse-power ..	50	75	100	125	150	200	250	300	350	400	500	600	700	800
Cost per H.P., \$	20	17½	16	15	14½	13½	13	12¾	12.6	12.6	12.8	13¼	14	15

**GEARING.**

**Efficiency of Worm Gearing.** (See also page 898)—Worm gearing as a means of transmitting power, has until recently, generally been looked upon with suspicion, its efficiency being considered necessarily low and its life short. Recent experience, however, indicates that when properly proportioned it is both durable and reasonably efficient. Mr. F. A. Halsey discusses the subject in *Am. Machinist*, Jan. 13 and 20, 1898. He quotes two formulas for the efficiency of worm gearing due to Prof. John H. Barr:

$$E = \frac{\tan \alpha (1 - f \tan \alpha)}{\tan \alpha + f}, \dots (1)$$

$$E = \frac{\tan \alpha (1 - f \tan \alpha)}{\tan \alpha + 2f} \text{ approx.}, \dots (2)$$

in which  $E$  = efficiency;  $\alpha$  = angle of thread, being angle between thread and a line perpendicular to the axis of the worm;  $f$  = coefficient of friction.

Eq. (1) applies to the worm thread only, while (2) applies to the worm and step combined, on the assumption that the mean friction radius of the two is equal. Eq. (1) gives a maximum for  $E$  when  $\tan \alpha = \sqrt{1 + f^2} - f \dots (3)$

and eq. (2) a maximum when  $\tan \alpha = \sqrt{2 + 4f^2} - 2f \dots (4)$  Using a value .05 for  $f$  gives a value for  $\alpha$  in (3) of  $43^\circ 34'$  and in (4) a value of  $52^\circ 49'$ .

On plotting equations (1) and (2) the curves show the striking influence of the pitch-angle upon the efficiency, and since the lost work is expended in friction and wear, it is plain why worms of low angle should be short-lived and those of high angle long-lived. The following table is taken from Mr. Halsey's plotted curves:

RELATION BETWEEN THREAD-ANGLE SPEED AND EFFICIENCY OF WORM GEARS.

Velocity of Pitch-line, feet per minute.	Angle of Thread.					
	5	10	20	30	40	45
	Efficiency.					
3	35	52	66	73	76	77
5	40	56	69	76	79	80
10	47	62	74	79	82	82
20	52	67	78	83	85	86
40	60	74	83	87	88	88
100	70	82	88	91	91	91
200	76	85	91	92	92	92

The experiments of Mr. Wilfred Lewis on worms show a very satisfactory correspondence with the theory. Mr. Halsey gives a collection of data comprising 16 worms doing heavy duty and having pitch-angles ranging between  $4^\circ 30'$  and  $45^\circ$ , which show that every worm having an angle above  $12^\circ 30'$  was successful in regard to durability, and every worm below  $9^\circ$  was unsuccessful, the overlapping region being occupied by worms some of which were successful and some unsuccessful. In several cases worms of one pitch-angle had been replaced by worms of a different angle, an increase in the angle leading in every case to better results and a decrease to poorer results. He concludes with the following table from experiments by Mr. James Christie, of the Pencoyd Iron Works, and gives data connecting the load upon the teeth with the pitch-line velocity of the worm:

LIMITING SPEEDS AND PRESSURES OF WORM GEARING.

	Single-thread Worm 1" Pitch, $2\frac{1}{2}$ " Pitch Diam.				Double-thread Worm 2" Pitch, $2\frac{1}{2}$ " Pitch Diam.			Double-thread Worm $2\frac{1}{2}$ " Pitch, $4\frac{1}{2}$ " Pitch Diam.		
	128	201	272	425	128	201	272	201	272	425
Revolutions per minute.....	128	201	272	425	128	201	272	201	272	425

**APPROXIMATE HYDRAULIC FORMULÆ.**

(The Lombard Governor Co., Boston, Mass.)

Head ( $H$ ) in feet. Pressure ( $P$ ) in lbs. per sq. in. Diameter ( $D$ ) in feet.  
Area ( $A$ ) in sq. ft. Quantity ( $Q$ ) in cubic ft. per second. Time ( $T$ ) in seconds.

$$\text{Spouting velocity} = 8.02 \sqrt{H}.$$

Time ( $T_1$ ) to acquire spouting velocity in a vertical pipe, or ( $T_2$ ) in a pipe on an angle ( $\theta$ ) from horizontal:

$$T_1 = 8.02 \sqrt{H} \div 32.17, \quad T_2 = 8.02 \sqrt{H} \div 32.17 \sin \theta.$$

Head ( $H$ ) or pressure ( $P$ ) which will vent any quantity ( $Q$ ) through a round orifice of any diameter ( $D$ ) or area ( $A$ ):

$$H = Q^2 \div 14.1D^4, \quad H = Q^2 \div 23.75A^2;$$

$$P = Q^2 \div 34.1D^4, \quad P = Q^2 \div 55.3A^2.$$

Quantity ( $Q$ ) discharged through a round orifice of any diameter ( $D$ ) or area ( $A$ ) under any pressure ( $P$ ) or under any head ( $H$ ):

$$Q = \sqrt{P \times 55.3 \times A^2}, \quad Q = \sqrt{P \times 34.1 \times D^4};$$

$$Q = \sqrt{H \times 23.75 \times A^2}, \quad Q = \sqrt{H \times 14.71 \times D^4}.$$

Diameter ( $D$ ) or area ( $A$ ) of a round orifice to vent any quantity ( $Q$ ) under any head ( $H$ ) or under any pressure ( $P$ ):

$$D = \sqrt{Q \div 3.84 \sqrt{H}}, \quad D = \sqrt{Q \div 5.8 \sqrt{P}};$$

$$A = Q \div 4.89 \sqrt{H}, \quad A = Q \div 7.35 \sqrt{P}.$$

Time ( $T$ ) of emptying a vessel of any area ( $A$ ) through an orifice of any area ( $a$ ) anywhere in its side:

$$T = .416A \sqrt{H} \div a.$$

Time ( $T$ ) of lowering a water level from ( $H$ ) to ( $h$ ) in a tank through an orifice of any area ( $a$ ) in its side. Area of tank is ( $A$ ).

$$T = 0.416A(\sqrt{H} - \sqrt{h}) \div a.$$

Kinetic energy ( $K$ ) or foot-pounds in water in a round pipe of any diameter ( $D$ ) when moving at velocity ( $V$ ):

$$K = .76 \times D^2 \times L \times V.$$

Time-average pressure ( $A.P.$ ) in a pipe of any length ( $L$ ) with water moving at any velocity ( $V$ ):

$$A.P. = 0.1324LV \div T.$$

Note.—This must not be confused with water-hammer pressure, which is always many times greater than  $A.P.$  and for which no simple formula may be written.

Area ( $a$ ) of an orifice to empty a tank of any area ( $A$ ) in any time ( $T$ ) from any head ( $H$ ):

$$a = T \div 0.409A \sqrt{H}.$$

Area ( $a$ ) of an orifice to lower water in a tank of area ( $A$ ) from head ( $H$ ) to ( $h$ ) in time ( $T$ ):

$$a = T \div 0.409 \times A \times (\sqrt{H} - \sqrt{h}).$$

**SPECIFICATIONS FOR TIN AND TERNE PLATE.**

(Penna. R. R. Co., 1902.)

Each sheet must (1) be cut as nearly exact to size ordered as possible, (2) must be rectangular and flat and free from flaws, (3) must double-seam successfully under all circumstances, (4) must show a smooth edge with no sign of fracture when bent through an angle of 180° and flattened down with a wooden mallet, (5) must be so nearly like every other sheet in the shipment, in thickness, uniformity, and amount of coating, that no difficulty will arise in the shops due to varying thickness of sheets, and (6) must correspond for the different grades to the figures in the following table :

Kind of Coating.	Tin Plate. Pure Tin.	No. 1 Terne Plate. ¼ Tin, ¾ Lead.	No. 2 Terne Plate. ¼ Tin, ¾ Lead.
Amt. of coating per sq. ft. . . .	0.0182 lb.	0.0364 lb.	0.0182 lb.
Grade IC. . . . weight per sq. ft	0.49	0.51	0.49
" IX . . . . " " "	0.62	0.64	0.62
" IXX . . . . " " "	0.71	0.73	0.71
" IXXX. . . . " " "	0.81	0.83	0.81
" IXXXX " " "	0.91	0.93	0.91

## LIST OF AUTHORITIES QUOTED IN THIS BOOK.

When a name is quoted but once or a few times only, the page or pages are given. The names of leading writers of text-books, who are quoted frequently, have the word "various" affixed in place of the page-number. The list is somewhat incomplete both as to names and page numbers.

## abb-alt

- Abbreviations, 1  
Abscissas, 69  
Abrasion of manganese steel, 407  
Abrasive processes, 965-967  
Absolute temperature, 461  
    zero, 461  
Absorption of gases, 480  
    of water by brick, 312  
    refrigerating-machines, 984  
Accelerated motion, 427  
Acceleration, definition of, 423  
    force of, 427  
    work of, 430  
Accumulators, electric, 1045-1048  
Adiabatic compression of air, 499  
    curve, 742  
    expansion of air, 501  
    expansion in compressed air-  
    engines, 501a  
    expansion of steam, 742  
Adiabatically compressed air, mean  
    effective pressures, table, 501b  
Admiralty metal, composition of,  
    325  
Admittance of alternating cur-  
    rents, 1063  
Aiken intensifier, 619  
Air, 481-527  
    and vapor mixture, weight of,  
    484  
    binds in pipes, 579  
    carbonic acid allowable in, 529  
    compressed, 498-511 (*see* Com-  
    pressed air)  
    compressors, effect of intake  
    temperatures, 506  
    compressors, high altitude, table  
    of, 503  
    compressors, tables, 503-505  
    cooling of, 531  
    density and pressure, 481, 482  
    flow of, in pipes, 485, 489  
    flow of, in ventilating ducts, 530  
    flow of through orifices, 484, 518  
    friction of, in underground pas-  
    sages, 531  
    head of, due to temperature dif-  
    ferences, 533  
    heating of, by compression, 498  
    horse-power required to com-  
    press, 501  
    loss of pressure of in pipes, 487;  
    tables, 488-490  
    manometer, 481  
    properties of, 481  
    pump for condenser, 841  
Air, specific heat of, 458, 484  
    lift pump, 614  
    pyrometer, 453  
    thermometer, 454  
    velocity of, in pipes, by anemom-  
    eter, 491  
    volumes, densities, and pressures  
    (table), 481  
    volume transmitted in pipes, 864  
    weight of, 165, 481; table, 484  
Alcohol, compressibility of, 164  
Alden absorption dynamometer,  
    979  
Algebra, 33-36  
Algebraic symbols, 1  
Alligation, 10  
Alloys, 319-338  
    aluminum, 328  
    aluminum, tests of, 330  
    aluminum-antimony, 331  
    aluminum-copper, 329  
    aluminum-copper-tin, 330  
    aluminum-silicon-iron, 330  
    aluminum-tin, 330  
    aluminum-tungsten, 330  
    aluminum-zinc, 330  
    antimony, 336  
    bearing metal, 333  
    bismuth, 332  
    caution as to strength of, 329  
    composition of, in brass foundries,  
    325  
    composition by mixture and by  
    analysis, 323  
    copper-manganese, 331  
    copper-tin, 319, 320  
    copper-tin-lead, 326  
    copper-tin-zinc, 322, 325  
    copper-zinc, 321  
    copper-zinc-iron, 326  
    fusible, 333  
    Japanese, 326  
    liquefaction of metals in, 323  
    nickel, 332  
    variation in strength of, 323  
    white metal, 336  
"Alloy" steels, 407-410  
Alternating currents, 1061-1078  
    admittance, 1063  
    average, maximum, and effective,  
    values, 1061  
    calculation of circuits, 1072  
    capacity, 1062  
    capacity of conductors, 1067  
    converters, 1071  
    delta connection, 1069

- Alternating currents, frequency,**  
 1061  
 generators for, 1070  
 impedance, 1063  
 impedance polygons, 1064-1066  
 inductance, 1062  
 induction motor, 1072, 1077  
 measurement of power in poly-  
 phase circuits, 1069  
 Ohm's law applied to, 1064  
 power factor, 1062  
 reactance, 1063  
 single and polyphase, 1068  
 skin effect, 1063  
 synchronous motors, 1071, 1076  
 transformers, 1070  
 Y connection, 1069  
**Altitude by barometer,** 483  
**Aluminum,** 167, 317  
 alloys, 319, 328 (*see* Alloys)  
 alloys, tests of, 330  
 brass, 329  
 bronze, 328  
 bronze wire, 225  
 electrical conductivity of 1028  
 solder, 319  
 steel, 409  
 strength of, 318  
 wire, 225  
**American base-box system,** 182  
**Ammonia-absorption refrigerating-**  
 machine, 984, 987; test of, 997  
**Ammonia-compression refrigerating-**  
 machines, 983, 986; test of,  
 999  
**Ammonia gas, properties of,** 992  
**Ammonia liquid, density of,** 992  
 specific heat of, 992  
**Ampere,** 1024  
**Analyses, asbestos,** 235  
 of boiler scale, 552  
 of boiler water, 553, 554  
 of cast iron, 371-374  
 of coals, 624-632  
 of coal, sampling for, 632  
 crucible steel, 411  
 fire-clay, 234  
 gas, 651  
 gases of combustion, 622  
 magnesite, 235  
**Analytical geometry,** 69-71  
**Anchor forgings, strength of,** 297  
**Anemometer,** 491  
**Angle, economical, of framed struc-**  
 tures, 447  
 of repose of building material  
 929  
**Angles, Carnegie bulb, properties**  
 of, table, 278  
 Carnegie steel, properties of,  
 table, 279a  
 Pencoyd steel, weights and sizes,  
 179  
 trigonometrical properties of, 66  
 plotting without protractor, 52  
 problems in, 37, 38  
**Angular velocity,** 425  
**Animal power** 433-435
- Annealing, effect on conductivity,**  
 1029  
 effect on steel, 392, 412  
 influence of on magnetic capac-  
 ity of steel, 396  
 non-oxidizing process of, 389  
 of steel, 394, 413  
 of steel forgings, 396  
 of structural steel, 394  
**Annuities, 15-17**  
**Annular gearing,** 898  
**Anthracite, classification of,** 624  
 composition of, 624  
 sizes of, 632  
 space occupied by, 625  
**Anthracite-gas,** 647  
**Anti-friction curve, 50, 939**  
 metals, 932  
**Antimony, properties of,** 167  
 in alloys, 331, 336  
**Apothecaries' measure and weight,**  
 18, 19  
**Arc, circular, 57**  
 circular, Huyghen's approxima-  
 tion of length of, 58; table, 114  
 circular, relations of, 58  
**Arc-lights, electric,** 1041  
**Arches, corrugated** 181  
 flooring, 281  
 tie-rods for, 281  
**Area of circles 1-1000, table, 103-**  
 107  
 of circles  $\frac{1}{8}$ -100, table advanc-  
 ing by  $\frac{1}{8}$ , 108-112  
 of geometrical solids, 61-63  
 of geometrical plane figures,  
 54-60  
 of irregular figures, 55, 56  
 of sphere, 61  
 of sphere, table, 118  
**Arithmetic, 2-32**

# Triplex Blocks

are available for almost every contracting and engineering work. They are the most efficient hand hoists made, and effect pronounced savings in time, labor and repair bills.

*Yale & Towne Chain Blocks* are constructed upon the most approved mechanical principles, and each part is carefully made and inspected. This makes each block absolutely safe and promotes ease of operation and long life.

TRIPLEX.—For greatest ease and quickness. 14 sizes.  $\frac{1}{2}$  to 20 tons.

DUPLEX.—For ease and handiness. 10 sizes.  $\frac{1}{2}$  to 10 tons.

DIFFERENTIAL.—The Cheapest reliable chain block. 7 sizes.  $\frac{1}{8}$  to 3 tons.

ELECTRIC HOIST.—Best where conditions justify it. 4 sizes. 1 to 6 tons.

*Catalogues and other information sent on request.*

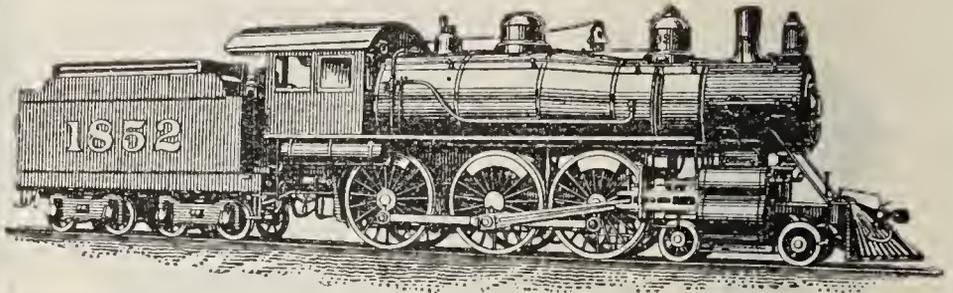

## The Yale & Towne Mfg. Co.

9 - 15 Murray Street, New York

*Local Offices:* Chicago, Boston, Philadelphia, San Francisco

# BALDWIN LOCOMOTIVE WORKS.

Burnham, Williams & Co.,  
Philadelphia, U. S. A.

## LOCOMOTIVES of all descriptions.

Mine and Furnace Locomotives operated by  
Steam, Compressed Air, and Electricity.

---

## The General Electric Company's

Type M Control

(Sprague-General Electric System)

FOR ELECTRIC TRAINS HAS BEEN ADOPTED EXCLUSIVELY BY THE NEW YORK UNDERGROUND RAILWAY.

(Interborough Rapid Transit Company)

ALL ELECTRIC TRAINS ON MANHATTAN ISLAND ARE  
EQUIPPED WITH THE SPRAGUE-GENERAL  
ELECTRIC SYSTEM OF CONTROL.

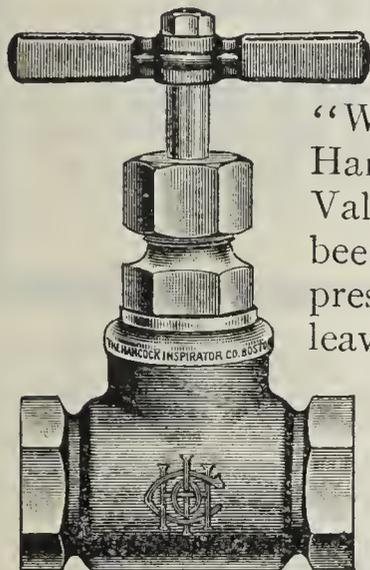

General Office: SCHENECTADY, N. Y.

New York Office: 44 Broad Street. Sales Offices in all large cities

# THE HANCOCK VALVES

Made in one grade **ONLY**

**FOR ALL KINDS OF SERVICE**

## OUR GUARANTEE

“We guarantee that each and every Hancock Globe, Angle, 60° and Cross Valve, with our monogram on it, has been tested with 1000 pounds water pressure and found tight before leaving the works.”

Write for our book of  
“Valves”

**The Hancock Inspirator Co.**

85-87-89 Liberty St.  
NEW YORK

22-24-26 So. Canal St.  
CHICAGO

# NATIONAL TUBE COMPANY,

MANUFACTURERS OF

LAP- AND BUTT-WELDED WROUGHT PIPE

( $\frac{1}{8}$  INCH TO 30 INCHES DIAMETER.)

# AIR POWER APPLIANCES

For thirty-five years the standards of  
progress in engineering work

AIR AND GAS COMPRESSORS  
ROCK DRILLS  
COAL-MINING MACHINERY  
STONE CHANNELERS  
PNEUMATIC PUMPING SYSTEMS  
PNEUMATIC TOOLS

Complete Pneumatic Power Equipments

*Descriptive literature sent on request*

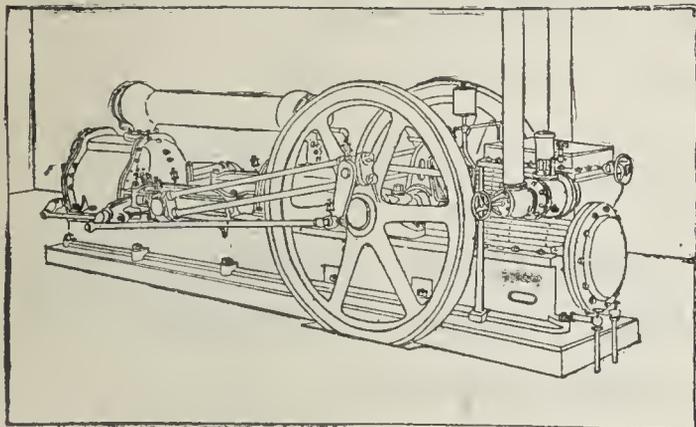

# INGERSOLL-RAND CO.

11 BROADWAY, NEW YORK

OFFICES IN ALL THE PRINCIPAL CITIES OF THE WORLD

# THE NORWALK AIR COMPRESSOR

OF STANDARD PATTERN

is built with Tandem Compound Air Cylinders. Corliss Air Valves on the intake cylinders insure small clearance spaces. The Intercooler between the cylinders saves power by removing the heat of compression before the work is done, not after, and the compressing is all done by a straight pull and push on a continuous piston rod. The Compressor is self-contained; the repair bills

are reduced to a minimum, and the machine is economical and efficient. Special machines for high pressures and for liquefying gases. Compound and Triple Steam Ends.

*A catalog, explaining its many points of superiority, is sent free to business men and engineers who apply to*

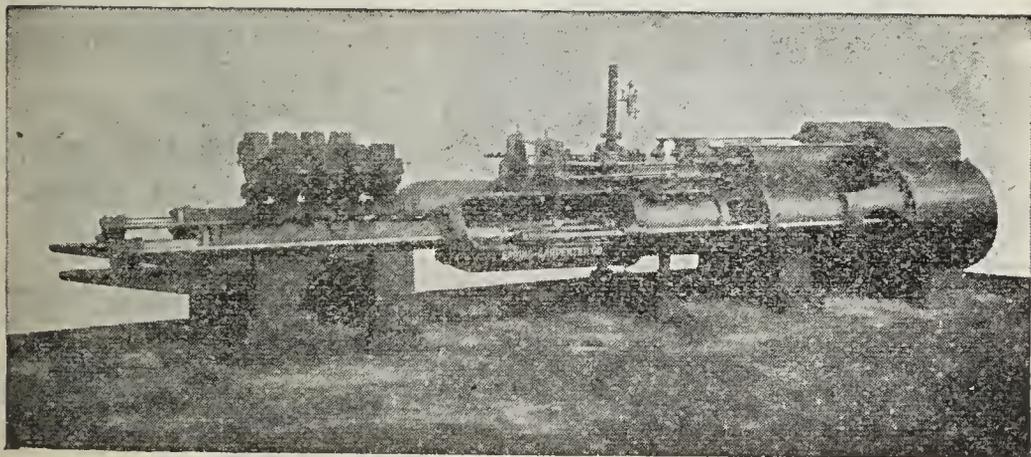

**THE NORWALK IRON WORKS CO.,**  
SOUTH NORWALK, CONN.

---

**EPPING-CARPENTER COMPANY,**

Rods for Yacht Shafting, Bolts, Pump Pistons; also Sheets, Tubes, Etc.

99 JOHN ST., NEW YORK CITY

---

*A Dozen Reasons why  
there is more "AMERICAN"<sup>TRANSMISSION</sup> ROPE  
used than all other brands combined:-*

- 1 *It is self lubricating-*
- 2 *Stretched in process of manufacture-*
- 3 *Outer yarns edged to retard external wear-*
- 4 *Pure Manila Hemp throughout-no spongy core-*
- 5 *Rope cut to exact lengths required--*
- 6 *Coils 10,000 ft long without a splice-*
- 7 *Large stock in all sizes insures prompt shipments-*
- 8 *Our expert splicers sent anywhere-*
- 9 *Expert consultation given upon request-*
- 10 *Drives designed & drawings furnished gratis-*
- 11 *No order too small or too large for us-*
- 12 *It is the finest example of the  
rope makers' art.*

*The AMERICAN MFG. CO.*

*65 WALL STREET NEW YORK.*

*"The Blue Book of Rope Transmission" free upon request.*

**"OLD COLONY"**

# **Transmission Rope**

---

Our Old Colony selected long fibre Manila Transmission Rope embodies every point of high quality and efficiency that long experience and scientific experiment have contributed to the art of rope making. It is the one rope on the market sold absolutely on its merits, its price being always based on the market value of the best marks of Cebu Manila hemp, of which it is made.

In the manufacture of Old Colony Rope the question of price is not considered, the purpose at all times being to better its quality, if possible, rather than to decrease its cost. In equipping your plant with Old Colony Rope you are getting absolutely the best that money can buy.

**GEO. B. CARPENTER & CO.**

200, 202, 204, 206, 208 S. Water St., Chicago
